

Labor Share and Aging Population

Fabien Petit*

October 17, 2019

Abstract

A large literature has studied multiple determinants of the labor share, but the age structure of the population has received little attention. This paper argues that demographic dynamics in high-income countries affect the labor share in two different ways: directly through the labor supply and the capital accumulation, and indirectly through the public policy. I use an OLG model in which a generation conflict arises because young and old generations have different income sources and opposite objectives in the public policy. The youth face an unemployment risk. They use their political power to cover it with government unemployment benefits at the cost of their elders. This fight over the public budget allocation has consequences for the wage bargaining and so the labor share. Numerical simulations for France and the United-States indicate that the model can replicate the data and that baby-boomers' cohorts have driven the labor share dynamics.

Keywords: Labor Share, Aging Population, Wage bargaining, Probabilistic voting.

1 Introduction

The labor income share is often assumed as constant by the economists. However, it has decreased during the last decades in OECD countries as emphasized by [Karabarbounis and Neiman \(2014\)](#) (see also [Elsby et al. 2013](#) for a detailed analysis of the US labor share). In the same time, high-income countries such as France and the United States experiment an aging population related to the existence of a larger cohort called the *baby-boomers*. Aging population and its consequences on macroeconomic variables have recently known an increasing interest as demonstrated by [Sheiner \(2014\)](#). Yet, the literature has paid little attention to the impact of population dynamics on the labor share. Those two phenomena, in high-income countries, raise the question of whether the age structure of the population is a factor affecting the way in which national income is allocated between labor and capital. Moreover, variations within the demographic structure may also affect the public policy by changing welfare state preferences. Many authors have shown the existence of intergenerational conflicts over the public budget allocation (see, for example, [Busemeyer et al. 2009](#); [Sørensen 2013](#)). The public policy determines labor market institutions which are key determinant of wage and employment and therefore the labor share. To the best of my knowledge, this paper is the first to investigate the long-run relationship between the demographic dynamics and the labor share through the age-related conflict in public policy which determines the rules of the wage bargaining.

I start by presenting a theoretical framework which links the age structure of the population to the labor share. I use a two-period overlapping generation (OLG) model with two types of households: young and old. Young households supply labor and earn a labor income while old households earn a capital income through their saving returns. The government levies taxes on both incomes. On one hand, the government provides unemployment benefits because young people face an unemployment risk; on the other hand, the government funds health spending to the elderly. The public budget allocation is a source of intergenerational conflict because any welfare improvement for a generation is done at

the cost of the other generation. The public policy is determined with a voting. The larger is a generation with respect to the other, the stronger is its political power and therefore the closer to its ideal public policy is this generation. Youth desire more redistribution and unemployment benefits. At the same time, the representative labor union bargains with the representative firm over wages. The out-of-work options of young agents are positively affected by the level of unemployment benefits but negatively by the tax rate. These options enable the representative union to bargain greater wages. However, greater wages reduce the labor demand of the representative firm and thus increases the capital-per-worker and the production-per-worker. The labor share can be defined as the ratio between the wage rate and the production-per-worker. Consequently, the net effect on the labor share depends on the elasticity of substitution between capital and labor.

But the wages are also determined by the amount of capital stock in the economy.

Consequently,

This paper is related to the extensive literature on the labor share. Multiple determinants have been analyzed by economists to explain its decline. The three main explaining factors are institutions, biased technical change and globalization. Furthermore, these factors are closely linked. Institutions affect the labor share through the labor market structure. [Blanchard \(1997\)](#) points out the role played by institutions in the persistence of shocks. He references and examines the adverse shifts in labor supply during the 1970s and in labor demand during the 1980s that occurred in Continental European countries. In principle, adverse supply shocks of the 1970s would have had an impact on employment and the labor share but only in the short run. Due to labor market institutions, such as adjustment costs, these shocks generate long lags in labor demand and thereby their persistence in the long-run. [Bentolila and Bertola \(1990\)](#) show the concern of firing cost in the firms' ability to hire and fire. Such a labor market institution constrains the firms and leads to increase the labor share in the short run. In addition to adjustment costs, [Bentolila and Saint-Paul \(2003\)](#) also highlight the role of workers' bargaining power to explain the gap between the

marginal product of labor and the wage.

Biased technical change is also a determinant of the labor share. [Acemoglu \(2002\)](#) argues that endogenous technical change can be directed towards one factor or another, thus generating a bias. The targeted factor is determined by two competing effects: the price effect and the market size effect. The former favors the scarce factor while the latter promotes the abundant factor. The relative strength of those two effects are closely linked to the value of the elasticity of substitution between factors. Therefore, factor abundance and factor prices are determinant of the labor share. In line with this result, [Karabarbounis and Neiman \(2014\)](#) show that the decrease in the relative price of investment goods induced firms to shift away from labor and toward capital. Others have developed models with factor-saving innovation (see, for example, [Zuleta 2008](#); [Peretto and Seater 2013](#)).

As previously mentioned, the determinants of the labor share are closely linked. [Caballero and Hammour \(1998\)](#) show the impact of labor market institutions on the capital accumulation. They argue that biased technical change is a response of firms in the long run to the ability of workers to obtain a high income share in the short run. This ability is owing to pro-labor income institutions. These institutions allow workers to grab part of the capital income in the short run. In order to thwart this appropriation, firms substitute labor with capital in the long run.

Some authors have shown that globalization has a negative effect on the labor share through different aspects. [Elsby et al. \(2013\)](#) mention offshoring as one of them. Due to trade liberalization, labor intensive components of the US supply chain are outsourced abroad where labor factor is cheaper. [Krugman \(2008\)](#) and [Bassanini and Manfredi \(2014\)](#) also support this argument.¹ An other explanation belongs to trade and capital account openness. The increasing mobility of goods and capital has negative consequences on the labor share. By either decreasing directly the wage bargaining power (see [Jayadev 2007](#)

¹However, [Krugman \(2008\)](#) argues that offshoring has a modest impact because developing countries are specialized in niche industries. But also due to vertical specialization industries, meaning that only simplest tasks are performed abroad and thereafter final products are assembled in developed countries.

and [Young and Tackett 2018](#)) or giving incentive to implement labor market reforms due to capital competition between countries as emphasized by [Pica \(2010\)](#). These reforms then reduces wage bargaining power. Finally, a more recent reasoning is developed by [Autor et al. \(2019\)](#) about “superstar firms”. Due to globalization, the most productive firms dominates their market. These superstar firms are characterized by high markups and low labor share. They reduce the aggregated labor share because they represent a growing share of the output.

This paper is also related to the literature on demographic dynamics and their implications on economic variables. This topic is not new in itself, many authors have already looked at it at micro and macro-levels (see [Clark et al. 1978](#) for a survey). The renewal is mainly motivated by the current and expected shift of the population structure in high-income countries.² This phenomenon presents serious challenges in many fields of the economy. Some authors have examined its impact on economic growth (see [van Groezen et al. 2005](#); [Soares 2005](#); [Bloom et al. 2010](#); [Lee and Mason 2010](#)). Others have investigated the sustainability of pension systems in such a context (see [Ono 2003](#); [de la Croix et al. 2013](#); [Philipov et al. 2014](#)) and discussed about the optimality and feasibility of pension reforms (see [Pecchenino and Pollard 1997](#); [Sinn and Uebelmesser 2003](#)). Related to the pension issue, the legal age of retirement is also probed (see [Futagami and Nakajima 2001](#); [Dedry et al. 2017](#)).

Besides all these challenges raised by population aging, the public budget allocation remains the main underlying political issue. This issue is related to the presence of an age-related conflict within the public policy. The youth and their elderly do not benefit from the same public policy instruments neither have the same type of income. Therefore, preferences are likely to change over the life-cycle. On one hand, [Sørensen \(2013\)](#) shows that elderly people desire less spending in education while they are in support of more in health and pension.³ However, the author claims that these life-cycle effects are quite small. On the other hand, [Busemeyer et al. \(2009\)](#) find sizable age-related differences in public policy

²See [Bloom and Luca \(2016\)](#) for a recent survey of the determinants of population aging.

³[Sørensen \(2013\)](#) uses cross-sectional survey data for 22 countries from the International Social Survey Program (ISSP). There are four Role of Government surveys corresponding to the years 1985, 1990, 1996 and 2006.

preferences.⁴ Although both studies disagree on the magnitude of the conflict, they both claim that such a conflict exists. They also agree about the heterogeneity among countries of these life-cycle effects. [Jäger and Schmidt \(2016\)](#) also assess the impact of demographic aging on public investment.⁵ They find a negative long-run relationship between both relying on the fact that older people discount more future payoffs with respect to young people.⁶

This paper relates to the literature on politico-economic models. This literature has started following the work of [Lindbeck and Weibull \(1987\)](#) on probabilistic voting. These models are useful to examine the relationship between redistribution policies and growth (see, for example, [Alesina and Rodrik 1994](#); [Persson and Tabellini 1994](#); [Krusell et al. 1997](#)). However, they are rather focused on intra-generational government budget allocation conflicts than inter-generational. Lately, some authors have brought these models back into use in order to analyze the age-related conflict between generations. [Lancia and Prarolo \(2012\)](#) develop an overlapping generations (OLG) model with three types of agents: young, adult and old. They focus their analysis on economic growth and find that an increasing life expectancy is a growth-enhancing factor. Economic growth is determined by two components: human capital growth and total factor productivity growth. First, young agents inherit the average human capital level of their parents and decide to invest on their education level. The higher is the expected life expectancy, the greater is the incentive to educate. Investing in education increases human capital. Second, all agents vote to determine the innovation public policy that fosters total factor productivity. This investment is done at the cost of public pensions. Thus, elderly are necessary opposed to innovation. When both, young and adults, are net winners from public investment policy, they form a coalition in the political process to adopt such a policy. Therefore, aging has two opposite effects on growth. On one hand, it generates incentives to human capital accumulation and innovation. On

⁴[Busemeyer et al. \(2009\)](#) use cross-sectional survey data for 14 OECD countries from the 1996 ISSP Role of Government dataset.

⁵[Jäger and Schmidt \(2016\)](#) use panel data of 19 OECD countries between 1971 and 2007.

⁶See, for example, [Harrison et al. \(2002\)](#); [Read and Read \(2004\)](#). See also [Huffman et al. \(2017\)](#) for a more recent empirical study with a decomposition by characteristics of time discounting in old population.

the other hand, it increases the political weight of elderly who are against innovation and makes policies more difficult to implement. With the same type of conflict on transfers to retired old households and public investment, [Gonzalez-Eiras and Niepelt \(2012\)](#) analyze implications for per-capita growth. However, they also endogenize the retirement age in a politico-economic equilibrium. They distinguish two effects: a direct one through the savings rate, labor supply and capital accumulation ; and an indirect one through the age-related conflict within the public policy to determine the levels of taxes, government spending and retirement age. They predict an increase of tax rates and the retirement age in OECD countries to offset population aging and thereby boost per-capita growth.

Despite the existing literature on the relationship between demographic dynamics and growth, the impact of demography on the income allocation between capital and labor has been understudied. To the best of my knowledge, [Schmidt and Vosen \(2013\)](#) is the only one paper to examine the impact of the demography on the labor share. Using an OLG model with pension system, they show that an aging population leads to more saving and so more capital. In a closed economy, the effect on the labor share depends on the value of the capital-labor elasticity of substitution. For an elasticity greater (resp. smaller) than unity, the effect is negative (resp. positive). While in a small economy with perfect capital mobility, they argue that households invest abroad because domestic interest rates fall. As a result, the increasing net foreign assets income shrinks the labor share. Their paper points out a link between the population aging and the labor share through capital accumulation. However, they do not consider any age-related conflict within the public budget allocation.

[Caballero and Hammour \(1998\)](#) incorporate the long-run response of firms to labor market institutions shaped in favor of workers. This response is the substitution of labor with capital. However, they do not look upstream to determine the reasons of such a labor market institutional context. In high-income countries, such as France and the United-States, the after-war period has been characterized by a colossal increase of the working-age population. Either with the so called baby-boomers cohort or the immigration. During the 1970s and the

1980s, this generation may have shaped the labor market institutions in their favor because they had enough political weight to do so. This period has been characterized by rising unionization, employment protection and unemployment benefits. All of these labor market institutions has raised real wages and therefore the labor cost for firms. In such a context, the argument of [Caballero and Hammour \(1998\)](#) fits perfectly. Firms have shifted from labor to capital in order to thwart workers empowerment.

In the continuity of their approach, I investigate the negative correlation between the aging population and the labor share. I consider an OLG model in a framework with probabilistic voting and wage bargaining. In addition of a change in capital stock, the labor share is also affected by outside options in the wage bargaining. These outside options are determined through the public policy where it exists an age-related conflict between young and old. I realize a quantitative analysis for France and the United-States. I also perform an aging-effect decomposition to analyze to which extent demographic determinants affect the labor share and through which channels. As [Gonzalez-Eiras and Niepelt \(2012\)](#), there are two determinants of demographic dynamics: population growth and survival rate (i.e. life expectancy). But also two transmission mechanisms: a direct one that is reflected in capital accumulation and labor supply ; and an indirect one through the public policy instruments.

Quantitative results suggest that the model is able to replicate long-run dynamics of the labor share in France and United-States. Demographic dynamics explain relatively better the French data pattern with respect to US data. This is due to the larger size of the welfare state and the greater disparity of cohort sizes in France. The declining labor share of the past decades was mainly driven by the baby-boomers cohort. Model predictions suggest that the aging of the baby-boomers cohort should generate a modest increase of the labor share for next decades. I find that the rising survival rate is a much more explaining factor of labor share dynamics than the declining population growth. I also find that the direct effect dominates the indirect one until 2010 and is dominated thereafter. Although the labor income share was declining due to policies implemented by baby-boomers, they were not

the losers over this period because they extracted part of the income of the elderly through redistribution.

The paper is organized as follows. Section 2 presents the theoretical framework. Section 3 presents the quantitative analysis. It starts with the analysis of model predictions and mechanisms. I then perform an aging-effect decomposition with counterfactual simulations. Section 4 discusses some results of the paper. Section 5 concludes.

2 Theoretical Framework

I develop a two-period OLG model in which there are two types of households: young and old. Young households are workers and old households are capitalists. The economy is closed and capital fully depreciates between two periods. Households determine the public policy through probabilistic voting. The public policy and more specifically labor market institutions impact the wage bargaining between the representative firm and the representative union. The wage bargaining also affects the desired public policy. Both jointly determine the state of the economy and therefore the labor share.

Households determine the public policy through a voting system maximizing their expected utility. While at the same time, the representative labor union bargains over wages with the representative firm. Both processes are independent and simultaneous. Thus, I assume that there is no coordination between households and the labor union. Indeed, the outcome of the voting process is determined by an aggregation of the individual households preferences. They cannot synchronize their vote with the representative union, neither the opposite. Therefore, the agents who operate within the wage bargaining take the voting outcome as given and vice versa.

2.1 Households

The demographic dynamic of young households is $N_t^y = n_t N_{t-1}^y$ with $n_t > 0$ the gross young population growth. While the demographic dynamic of old households is $N_t^o = p_t N_{t-1}^o$ with $p_t \in (0, 1]$ the survival rate.⁷ Both demographic parameters follow deterministic processes. Thus, the old-age dependency ratio is $N_t^o/N_t^y = p_t/n_t$. The whole population is therefore $N_t = N_t^y + N_t^o$.

Each cohort consists of a continuum of homogeneous agents. Young households in period t supply labor inelastically, earn a net income, consume and save for retirement. They face an idiosyncratic longevity risk: with probability p_{t+1} they survive to become old households in period $t+1$. Once old, they pay taxes on their saving returns, consume and derive utility from government health spending. Finally, old households die at the end of the period. Savings of young agents who die before reaching old age are distributed among their surviving peers, reflecting a perfect annuities market.

Households derive utility from consumption when young $c_{1,t}$ and old $c_{2,t+1}$. Once old, they also value government health expenditure h_{t+1} . Agents discount the future at factor $\alpha \in (0, 1)$. Due to risk of death, the effective discount factor of young households equals αp_{t+1} .⁸ I assume that period utility functions are logarithmic. In first period, they earn a net income y_t to allocate between consumption and savings s_t . In second period, they consume the net return of their savings $(1 - \tau_{t+1})s_t \hat{R}_{t+1}$, where τ_{t+1} is the tax rate and \hat{R}_{t+1} the gross return on savings of a young household that survives to old age⁹. Maximizing

⁷The survival rate p_t is an increasing function of the life expectancy and a decreasing function of the retirement age. In the model, agents are considered as old once they retire. If the life expectancy and the retirement age grow at the same rate, then the survival rate remains constant. For more details on the measurement of population aging, see [Sanderson and Scherbov \(2007\)](#); [Sanderson and Scherbov \(2013\)](#); [D'Albis and Collard \(2013\)](#).

⁸Since the expected survival rate p_{t+1} is an increasing function of the expected life expectancy. The longer an agent expects to live, the less they discounts future.

⁹Due to perfect annuity market $\hat{R}_t = R_t/p_t$ where R_t is the gross return on physical capital.

expected utility, a household in period t solves the following maximization problem:

$$\begin{aligned} \max_{\{c_{1,t}, c_{2,t+1}\} \geq 0} & \ln(c_{1,t}) + \alpha p_{t+1} \{\ln(c_{2,t+1}) + \beta \ln(h_{t+1})\} \\ \text{s.t.} & \begin{cases} c_{1,t} + s_t = y_t \\ c_{2,t+1} = (1 - \tau_{t+1}) s_t \hat{R}_{t+1} \end{cases} \end{aligned}$$

where $\beta > 0$ characterizes the preference for health expenditure. Solving the household maximization problem, I obtain the optimal consumption in both period and savings in first period for a household of type $i \in \{e, u\}$:

$$\begin{aligned} c_{1,t}^i &= \frac{1}{1 + \alpha p_{t+1}} y_t^i \\ c_{2,t+1}^i &= \frac{\alpha p_{t+1}}{1 + \alpha p_{t+1}} (1 - \tau_{t+1}) \hat{R}_{t+1} y_t^i \\ s_t^i &= \frac{\alpha p_{t+1}}{1 + \alpha p_{t+1}} y_t^i \end{aligned}$$

Since the utility function is logarithmic, this is a standard result where the saving is a constant proportion of the income. Each household faces an idiosyncratic unemployment risk with probability $u_t \in [0, 1)$. The income of an employed young agent is $y_t^e = (1 - \tau_t)w_t$, while an unemployed young agent earns $y_t^u = b_t$, where w_t is the wage and b_t the unemployment benefits per capita. The aggregate saving in the economy is $S_t = (1 - u_t)N_t^y s_t^e + u_t N_t^y s_t^u$. Thus,

$$S_t = \frac{\alpha p_{t+1}}{1 + \alpha p_{t+1}} [(1 - u_t)(1 - \tau_t)w_t + u_t b_t] N_t^y \quad (1)$$

The indirect utility of an old household at time t depends on its income in $t - 1$. Hence,

$$U_t^{o,i} = \ln \left(\frac{\alpha p_t}{1 + \alpha p_t} (1 - \tau_t) y_{t-1}^i \hat{R}_t \right) + \beta \ln(h_t) \quad \forall i = \{e, u\} \quad (2)$$

The indirect utility of a young household at time t is:

$$U_t^{y,i} = \ln \left(\frac{1}{1 + \alpha p_{t+1}} y_t^i \right) + \alpha p_{t+1} U_{t+1}^{o,i} \quad \forall i = \{e, u\}$$

Computing the gap between employed and unemployed people in utility terms, I have:

$$U_t^{y,e} - U_t^{y,u} = (1 + \alpha p_{t+1}) \ln \left[\frac{(1 - \tau_t) w_t}{b_t} \right] \quad (3)$$

Moreover, the expected income of each young household is a weighted average of both incomes (labor income and unemployment benefits). Thus, $\mathbb{E}(y_t) = (1 - u_t)(1 - \tau_t)w_t + u_t b_t$, where \mathbb{E} is the expectation operator. Computing the expected utility of a young household at time t , I obtain:

$$\mathbb{E}(U_t^y) = \ln \left(\frac{\mathbb{E}(y_t)}{1 + \alpha p_{t+1}} \right) + \alpha p_{t+1} \left\{ \ln \left(\frac{\alpha p_{t+1}}{1 + \alpha p_{t+1}} (1 - \tau_{t+1}) \mathbb{E}(y_t) \hat{R}_{t+1} \right) + \beta \ln(h_{t+1}) \right\} \quad (4)$$

2.2 Production

Firms are represented by a representative firm that uses a standard CES production function given by:

$$Y_t = A \left[\phi K_t^{\frac{\sigma-1}{\sigma}} + (1 - \phi) L_t^{\frac{\sigma-1}{\sigma}} \right]^{\frac{\sigma}{\sigma-1}} \quad (5)$$

where K_t is the capital stock, L_t the labor, σ the elasticity of substitution between capital and labor, ϕ the factor share parameter allowing the relative importance of inputs in production to vary and A a constant scale parameter. I do not consider any form of technical change, whether neutral or biased. Rewriting the production function in units of labor,

$$\frac{Y_t}{L_t} = A \left(\phi k_t^{\frac{\sigma-1}{\sigma}} + 1 - \phi \right)^{\frac{\sigma}{\sigma-1}} \quad (6)$$

where $k_t \equiv K_t/L_t$ is the capital-per-worker (i.e. capital intensity). Since the economy is closed and capital fully depreciates between two periods, the capital in the economy is determined by the saving of the previous period, i.e. $K_t = S_{t-1}$. The labor-demand equation obtained from the profit maximization of the representative firm is:

$$w_t = (1 - \phi)A \left(\phi k_t^{\frac{\sigma-1}{\sigma}} + 1 - \phi \right)^{\frac{1}{\sigma-1}} \quad (7)$$

The labor demand elasticity is defined as $\mathcal{E}_t^{L,w} = \frac{\partial L_t}{\partial w_t} \frac{w_t}{L_t}$. Using the equation (7),

$$\mathcal{E}_t^{L,w} = -\sigma \left(1 + \frac{1 - \phi}{\phi} k_t^{\frac{1-\sigma}{\sigma}} \right) \quad (8)$$

Using equations (6) and (7), I compute the labor share $\theta_t = \frac{w_t L_t}{Y_t}$ which is:

$$\theta_t = \left(1 + \frac{\phi}{1 - \phi} k_t^{\frac{\sigma-1}{\sigma}} \right)^{-1} \quad (9)$$

This equation holds if and only if the representative firm is on its labor demand curve. Notice that when the capital-labor elasticity of substitution equals unity, then $\theta_t = 1 - \phi$. In this case, the production function is Cobb-Douglas and the labor income share is constant in k_t . When $\sigma \rightarrow 0$, the production function is Leontief. When $\sigma \rightarrow +\infty$, the production function is linear. As long as the representative firm is not constrained in its ability to hire and fire workers, it means that the firm is on its labor demand curve and thereby the labor share only depends on k_t .¹⁰

The comparative statics are straightforward,

$$\left\{ \frac{\partial w_t}{\partial k_t} > 0, \quad \frac{\partial(Y_t/L_t)}{\partial k_t} > 0, \quad \frac{\partial \theta_t}{\partial k_t} \leq 0 \right\}, \quad \sigma \geq 1$$

A higher capital-labor ratio increases the wage resulting from the labor demand equation

¹⁰Considering a small open economy (SOE), the capital-labor ratio becomes constant. [Schmidt and Vosen \(2013\)](#) show that, in such a case, the labor share dynamics only reflects variations in net foreign assets of the economy.

and the production-per-worker. However, the impact on the labor share depends on the elasticity of substitution between both input factors. When capital and labor are gross substitute (i.e. $\sigma > 1$), a higher capital-labor ratio decreases the labor share. While the relationship is positive when both input factors are gross complement (i.e. $\sigma < 1$). Since the labor share can be defined as the ratio between wage and production-per-worker, it means that with gross substitute input factors, a rise of the capital-per-worker increases more the production-per-worker relatively to the wage rate. Vice versa when $\sigma < 1$. Thus,

$$\left\{ \frac{\partial w_t}{\partial k_t} \leq \frac{\partial(Y_t/L_t)}{\partial k_t} \right\}, \quad \sigma \geq 1$$

In order to have a negative relationship between the capital-to-labor ratio and the labor share without the presence of biased technical change, both input factors must be gross substitute (i.e. $\sigma > 1$).

2.3 Public policy preferences

The government taxes the labor income of young households and the savings return of old households in period t at rate τ_t . The government revenue is shared between unemployment benefits and health expenditure. Thus, the government budget constraint is the following: $\tau_t(w_t(1 - u_t)N_t^y + R_tS_{t-1}) = b_t u_t N_t^y + h_t N_t^o$. Capital fully depreciates between two periods, thus $R_t = r_t$ and $K_t = S_{t-1}$, where r_t is the rental price of capital. Therefore, the government budget constraint can be written as follows:

$$\tau_t Y_t = b_t u_t N_t^y + h_t N_t^o \quad (10)$$

Young and old agents have different objectives. Young households desire more unemployment benefits since they cover the risk to be unemployed. While the elderly desire more health spending because they derive utility from it. *Everything else equal*, both desire less taxes as it reduces their disposable income. I modelize the age-related conflict in public policy

with this trade-off but it could be extended to other public policy instruments. The central point is to oppose young and old households with different returns in utility terms of policy instruments.

[Sørensen \(2013\)](#) analyzes cross-section survey data for 22 countries and shows that agents change their public spending preferences over their life-cycle. Thus, he provides evidence for an age-related selfishness in public spending preferences. However, this effect tends to be small and heterogeneous across countries. He argues that a gerontocracy is not very likely. In line with these results, I consider a probabilistic voting setup in contrast to the median voter setup. This latter setup would create two extreme regimes with one of them being a gerontocracy. It would also generate large changes in public policy if the median-voter switches from young to old or vice versa. Under probabilistic voting, the equilibrium policy platform is a continuous function of the old-age dependency ratio. This setup smooths public policy changes in line with the literature of recent politico-economic models.

With probabilistic voting, all agents vote for a policy platform $g_t = (\tau_t, b_t, h_t)$ represented by opportunistic candidates (or parties). Candidates try to maximize their probability to win the election. They differ in their popularity and there is an idiosyncratic bias among voters for one candidate or the others. Candidates know about these biases. At the equilibrium, all candidates choose the same policy platform g_t^* that maximize the political objective function $W_t(g_t)$.¹¹

This function depends on population share of each voter groups and their respective sensitivity of voting behavior to policy changes ω^i . There are three groups of voter: young households; and old households who are divided in two subgroups according to their employment situation during the previous period because they did not earn the same income when they were young. Henceforth, they do not have the same saving returns and differ in their indirect utility (i.e. $U_t^{o,u}$ and $U_t^{o,e}$ given by (2)). However, I assume that all the elderly have the same sensitivity $\omega^o = \omega^{o,u} = \omega^{o,e}$. Thus, the equilibrium public policy solves the

¹¹See [Lindbeck and Weibull \(1987\)](#) for more details on the probabilistic-voting setup.

following maximization program:

$$\begin{aligned} \max_{g_t} \quad & W_t(g_t) = \frac{N_t^y}{N_t} \omega^y \mathbb{E}[U_t^y(g_t)] + \frac{N_t^o}{N_t} \omega^o \left\{ u_{t-1} U_t^{o,u}(g_t) + (1 - u_{t-1}) U_t^{o,e}(g_t) \right\} \\ \text{s.t.} \quad & (2), (4), (10) \end{aligned}$$

I assume that households only care about direct effects of public policy on their utility. They do not consider indirect effects of public policy on their utility that would pass through economic variables.¹² Let \tilde{U}_t^i be the part of the utility which is directly affected by the public policy platform. From (2), it is straightforward that $\tilde{U}_t^o = \tilde{U}_t^{o,u} = \tilde{U}_t^{o,e}$. Therefore, the political objective function can be rewritten as:

$$W_t(g_t) = \frac{N_t^o}{N_t} \omega^o \tilde{U}_t^o(g_t) + \frac{N_t^y}{N_t} \omega^y \tilde{U}_t^y(g_t) + \dots$$

where \dots denotes all the terms that are not directly affected by the public policy. Let ω be the *relative ideological spread-out* of the elderly with respect to the youth. This relative ideological spread-out is characterized by the ratio of the sensitivities of voting behavior to policy changes for each group. Thus, $\omega \equiv \omega^o / \omega^y$. I assume that this spread-out is constant over time.¹³ Using equations (2) and (4), I rewrite the maximization program that characterize the public policy equilibrium as:

$$\begin{aligned} \max_{\{\tau_t, b_t, h_t\} \geq 0} \quad & W_t(\tau_t, b_t, h_t) = \ln(1 - \tau_t) + \beta \ln(h_t) + \eta_t \ln[(1 - u_t)(1 - \tau_t)w_t + u_t b_t] + \dots \\ \text{s.t.} \quad & \tau_t Y_t = b_t u_t N_t^y + h_t N_t^o \end{aligned}$$

¹²An interpretation of this assumption is that agents are not able to predict what will be the response of the labor market to changes in public policy. Otherwise stated, the investment of effort to be perfectly informed and able to calculate indirect effects of different public policies is too costly for an individual (or at least a representative share of the electorate). Thus, the rationality is limited to direct effects on the utility function. This is related to political science literature and the concept of *synoptic rationality*. See Meier (1980) for more details.

¹³Two interpretation are plausible for this assumption: either both relative ideological spread-outs are time invariant; or they vary in same proportions. An interesting point would be to endogenize these spread-outs or to make them cohort-specific. Nevertheless, this goes beyond the scope of this paper.

where $\eta_t = \frac{n_t}{p_t} \frac{1+\alpha p_{t+1}}{\omega}$ is the youth political weight. This variable is the channel through which the age structure affects the public policy. It depends negatively on the old-age dependency ratio p_t/n_t , the older the population the lower the political weight of the youth within the policy determination. It also depends negatively on the relative ideological spread-out ω . The less ideological is the youth, the higher will be its political weight. If young people are less ideologically tenacious, then they are easier to convince with an appropriated public policy. As a consequence, candidates pay more attention to them.¹⁴ η_t is increasing in αp_{t+1} corresponding to the fact that young voters are more likely to swing in favor of a pro-labor-income policy platform. Because the longer they expect to live, the more they will have to save in order to smooth their consumption. Therefore, they require a relatively greater income which can only be a labor one.

Focusing on the interior solution, first order conditions lead to the following public policy preferences:

$$\frac{b_t}{(1-\tau_t)w_t} = \frac{1-u_t}{u_t} \left(\eta_t \frac{1-\theta_t}{\theta_t} - 1 \right) \quad (11)$$

$$\tau_t = 1 - [(1-\theta_t)(1+\beta+\eta_t)]^{-1} \quad (12)$$

$$h_t N_t^o = \frac{\beta}{1+\beta+\eta_t} Y_t \quad (13)$$

Where the first equation is the unemployment replacement rate, the second the tax rate and the third the government health expenditure. Some comparative statics about previous results are straightforward,

$$\left\{ \frac{\partial \frac{b_t}{(1-\tau_t)w_t}}{\partial \eta_t} > 0, \frac{\partial \tau_t}{\partial \eta_t} > 0, \frac{\partial h_t}{\partial \eta_t} < 0 \right\}$$

Young generations desire more redistribution and a higher unemployment replacement rate because they face an unemployment risk. Such a public policy allows them to increase their

¹⁴Otherwise stated, the less spread-out is the ideology distribution within a group, the more numerous to swing are the voters after changes in public policy platform.

expected income. However, they vote to reduce the government health spending because they do not derive utility from it yet.¹⁵

The aggregated income of young households is $Y_t^y = [(1 - u_t)(1 - \tau_t)w_t + b_t u_t] N_t^y$. Using equation (11) and (12), it can be written as a share of the total income Y_t such that:

$$Y_t^y = \frac{\eta_t}{1 + \beta + \eta_t} Y_t$$

The government health spending for old households is given by equation (13). The total income is split between incomes of both groups and the government health spending. Thus, $Y_t = Y_t^y + Y_t^o + h_t N_t^o$. Hence, the remaining part of the total income is the aggregated income of the elderly:

$$Y_t^o = \frac{1}{1 + \beta + \eta_t} Y_t$$

For a given level of total income Y_t , the comparative statics are unambiguous. When the youth political weight raises ($\eta_t \nearrow$), young households increase their aggregated income with more redistribution (i.e. $\frac{\partial Y_t^y}{\partial \eta_t} > 0$). Conversely, the aggregated income of the elderly decreases (i.e. $\frac{\partial Y_t^o}{\partial \eta_t} < 0$) and so does the government health spending (i.e. $\frac{\partial (h_t N_t^o)}{\partial \eta_t} < 0$). Such a raise may be due to two reasons: either a decrease of the old-age dependency ratio ($p_t/n_t \searrow$) or an increase of the survival rate of the current young generation ($p_{t+1} \nearrow$). The first reason is directly related to the old-age related conflict within the public policy. However, the second reason open onto an important point of the aging population. p_{t+1} can be interpreted as the expected life expectancy. Expecting to live longer, agents save more in order to smooth their consumption for the second period.¹⁶ From equation (1), the saving share of the aggregated income of young households is increasing in life expectancy. Therefore, a longer expected life expectancy leads to more savings and thus more available

¹⁵I do not consider any form of explicit altruism. However, the parameter β which is the preference for government health spending captures a form of altruism from young to their elders. The greater the parameter, the more individuals care about government health spending once old. Finally, a form of explicit altruism from young to old generations would smooth the results and soften the age-related conflict.

¹⁶See, for example, Bloom et al. (2003); Zhang and Zhang (2005).

capital for the next period. Furthermore, it is possible to express the after-tax income ratio between young and old households as:

$$\frac{Y_t^y}{Y_t^o} = \eta_t \quad (14)$$

As expected, the greater is the political weight of the youth, the greater is the redistribution and so is the gap between both incomes. These public policy instruments interact with the outcome of the wage bargaining to determine the state of the economy.

2.4 Wage bargaining

There is a single union that represents the workers. In order to modeling the wage bargaining, I consider a “Right-to-manage” model *à la* [Nickell and Andrews \(1983\)](#). The union bargains only over wages with the employer retaining the prerogative to hire and fire.¹⁷ Consequently, the firm is always on its labor demand curve and equation (7) holds. The union wants to maximize the workers’ utility compared to the unemployed people’s one (i.e. $U_t^{y,e} - U_t^{y,u}$) as described by (3). The representative firm maximizes its outside option which is $Y_t - w_t L_t$ corresponding to $r_t K_t$. Thus, the outcome of the bargaining process is determined by the maximization program as follows:

$$\begin{aligned} \max_{w_t > 0} \quad & \{(L_t[U_t^{y,e} - U_t^{y,u}])^\gamma (Y_t - w_t L_t)^{1-\gamma}\} \\ \text{s.t.} \quad & U_t^{y,e} - U_t^{y,u} = (1 + \alpha p_{t+1}) \ln \left[\frac{(1 - \tau_t)w_t}{b_t} \right] \end{aligned}$$

¹⁷Another possibility would have been to consider an “Efficient contract” model *à la* [McDonald and Solow \(1981\)](#) where the union bargains over wages and employment. However, this specification does not correspond to the data as [Bentolila and Saint-Paul \(2003\)](#) showed. Moreover, it would add a lot of complexity to the model without a substantial gain in the analysis.

where $\gamma \in (0, 1)$ is the relative bargaining power of the union. The first-order condition can be expressed as:

$$\frac{\gamma}{1-\gamma} \left\{ \mathcal{E}_t^{L,w} \ln \left[\frac{(1-\tau_t)w_t}{b_t} \right] + 1 \right\} = \ln \left[\frac{(1-\tau_t)w_t}{b_t} \right] \frac{w_t L_t}{Y_t - w_t L_t}$$

where $\mathcal{E}_t^{L,w}$ is the labor demand elasticity. Using the equations (8) and (9) within the first-order condition of the wage bargaining, I can express the capital-per-worker as a function of the unemployment replacement rate:

$$k_t(X_t) = \left[\frac{1-\phi}{\phi} \frac{1-\gamma(1-\sigma)}{\gamma} \frac{X_t}{1-\sigma X_t} \right]^{\frac{\sigma}{\sigma-1}} \quad (15)$$

where $X_t = \ln \left[\frac{(1-\tau_t)w_t}{b_t} \right]$ is the value-added to be employed in utility terms which only depends on the unemployment replacement rate. Since the capital-per-worker has to be positive, it implies that $1 - \sigma X_t > 0$. The maximum capital-labor elasticity of substitution ensuring that this condition is met can be defined as the function $\bar{\sigma}(x) = -\log^{-1}(x)$, where x is the unemployment replacement rate. Figure 1 plots this function for all values of the unemployment replacement rate between 0 and 0.8. The minimum unemployment replacement rates for France and the United-States over the period 1970-2010 correspond, respectively, to 0.592 and 0.567. Hence, the condition is met for all σ between zero and 1.907 for France or 1.762 for the United-States. For the remaining part of the paper, I assume that $\frac{1}{X_t} > \sigma$ is always satisfied. Comparative statics with respect to X_t are the following:

$$\left\{ \frac{\partial k_t}{\partial X_t} \geq 0 \Rightarrow \left\{ \frac{\partial w_t}{\partial X_t} \geq 0, \quad \frac{\partial(Y_t/L_t)}{\partial X_t} \geq 0, \quad \frac{\partial w_t}{\partial X_t} < \frac{\partial(Y_t/L_t)}{\partial X_t} \right\} \Rightarrow \frac{\partial \theta_t}{\partial X_t} < 0 \right\}, \quad \sigma \geq 1$$

When the unemployment replacement rate increases ($\frac{b_t}{(1-\tau_t)w_t} \nearrow$), it decreases the value-added to have a job ($X_t \searrow$). Hence, the labor share increases ($\theta_t \nearrow$). As an interpretation, when the unemployment replacement rate increases it allows the union to bargain a higher wage and so to grab a relatively larger share of the income. This mechanism holds whatever

Figure 1: Maximum capital-labor elasticity of substitution $\bar{\sigma}$

Unemployment replacement rate data are from the [Comparative Welfare Entitlements Dataset 2 \(CWED 2\)](#), see [Scruggs et al. \(2017\)](#) for more details.

the value of the capital-labor elasticity of substitution (i.e. σ). This is an interesting result in the sense that usually CES production functions give rise to results with a threshold on the value of σ with respect to unity. However, intermediate partial derivatives are just transitional and consider only the partial effect of a change in the unemployment replacement rate. Due to the endogeneity of w_t , I save the mechanisms analysis for later.

2.5 Equilibrium

Voting and wage bargaining take place simultaneously and there is no-coordination between both of them. As a consequence, both processes take the outcome of the other as given. The interaction determines the state of the economy. Expressing equations (11) and (15) in the value of being employed X_t as a function of the capital-to-labor ratio. The capital-to-labor

ratio k_t at the equilibrium solves:

$$X_t = \ln \left(\frac{\frac{N_t^y}{K_t} k_t - 1}{\frac{\phi}{1-\phi} k_t^{\frac{\sigma-1}{\sigma}} \eta_t - 1} \right) \quad (16)$$

$$X_t = \left(\sigma + \frac{1-\phi}{\phi} \frac{1-\gamma(1-\sigma)}{\gamma} k_t^{\frac{1-\sigma}{\sigma}} \right)^{-1} \quad (17)$$

The Cobb-Douglas case (i.e. $\sigma = 1$) can be solved analytically and leads to the following equilibrium:

$$X_t = \frac{\gamma}{1-\phi(1-\gamma)}$$

$$k_t = \left[1 + e^{X_t} \left(\frac{\phi}{1-\phi} \eta_t - 1 \right) \right] \frac{K_t}{N_t^y}$$

The value-added to have a job X_t is constant. The capital-per-worker k_t is still determined by demographic variables and is proportional to the capital-per-young individual. However, this case is not really useful to determine labor share's dynamics. Because the labor share becomes constant over time from equation (9), i.e. $\theta_t = 1 - \phi$. Otherwise, there is uniqueness of the equilibrium for any other value of sigma. Proof in [appendix A](#). The equilibrium is

characterized by 13 equations:

$$\eta_t = \frac{n_t}{p_t} \frac{1 + \alpha p_{t+1}}{\omega} \quad (\text{Pub. } \eta)$$

$$X_t = \ln \left(\frac{\frac{N_t^y}{K_t} k_t - 1}{\frac{\phi}{1-\phi} k_t^{\frac{\sigma-1}{\sigma}} \eta_t - 1} \right) \quad (\text{Eq. } g)$$

$$X_t = \left(\sigma + \frac{1-\phi}{\phi} \frac{1-\gamma(1-\sigma)}{\gamma} k_t^{\frac{1-\sigma}{\sigma}} \right)^{-1} \quad (\text{Eq. } h)$$

$$L_t = \frac{K_t}{k_t} \quad (\text{Prod. } L)$$

$$w_t = A(1-\phi) \left(\phi k_t^{\frac{\sigma-1}{\sigma}} + 1 - \phi \right)^{\frac{1}{\sigma-1}} \quad (\text{Prod. } w)$$

$$Y_t = A \left[\phi K_t^{\frac{\sigma-1}{\sigma}} + (1-\phi) L_t^{\frac{\sigma-1}{\sigma}} \right]^{\frac{\sigma}{\sigma-1}} \quad (\text{Prod. } Y)$$

$$u_t = 1 - \frac{L_t}{N_t^y} \quad (\text{Prod. } u)$$

$$\theta_t = \left(1 + \frac{\phi}{1-\phi} k_t^{\frac{\sigma-1}{\sigma}} \right)^{-1} \quad (\text{Prod. } \theta)$$

$$\tau_t = 1 - [(1-\theta_t)(1+\beta+\eta_t)]^{-1} \quad (\text{Pub. } \tau)$$

$$b_t = (1-\tau_t) w_t e^{-X_t} \quad (\text{Pub. } b)$$

$$h_t = \frac{\tau_t Y_t - b_t u_t N_t^y}{N_t^o} \quad (\text{Pub. } h)$$

$$S_t = \frac{\alpha p_{t+1}}{1 + \alpha p_{t+1}} [(1-\tau_t) w_t (1-u_t) + b_t u_t] N_t^y \quad (\text{HH. } S)$$

$$K_{t+1} = S_t \quad (\text{HH. } K)$$

Let define, respectively, equations (16) and (17) with the functions $g(L_t, K_t, \eta_t, N_t^y; \phi, \sigma)$ and $h(L_t, K_t; \sigma, \phi, \gamma)$, such as:

$$X_t = g(L_t, K_t, \eta_t, N_t^y; \phi, \sigma)$$

$$X_t = h(L_t, K_t; \sigma, \phi, \gamma)$$

Differentiating this system,

$$\begin{aligned} dX_t &= g_L dL_t + g_K dK_t + g_\eta d\eta_t + g_{N^y} dN_t^y \\ dX_t &= h_L dL_t + h_K dK_t \end{aligned}$$

where f_x is the partial derivative of the f function with respect to the variable x , e.g. $g_L = \frac{\partial g}{\partial L_t}$. Solving the system,

$$dL_t = \frac{1}{h_L - g_L} [(g_K - h_K) dK_t + g_\eta d\eta_t + g_{N^y} dN_t^y]$$

The variables η_t and N_t^y are given by demographic dynamics. The capital stock K_t is given by the savings of the previous period. Thus, the variable that determines the equilibrium is the level of employment L_t . Partial derivatives are derived in [appendix B](#). g_η is negative because the greater is the youth political power, the greater are the unemployment benefits and so the smaller is the value-added to have a job in utility terms. g_{N^y} is positive because the more numerous are the young individuals, the more these unemployment benefits are divided among them and so the smaller is the value-added to have a job in utility terms. $g_K - h_K$ depends on the value of σ with respect to unity, i.e. $g_K - h_K \leq 0, \forall \sigma \geq 1$. This is directly related to the fact that both input factors are either gross substitute or gross complement. When labor and capital are gross substitute, more available capital stock requires less labor for a given level of output. Otherwise, when both are complement, the representative firm has to jointly increase labor with capital stock in order to maintain the same production level. Finally, the sign of $h_L - g_L$ is ambiguous regardless of the value of σ . When $\sigma < 1$, then g_L and h_L are both positive. Thus, $g_L - h_L$ is ambiguous. When $\sigma > 1$, h_L is unambiguously negative. But the sign of g_L cannot be determined without additional assumptions. If $\frac{\eta_t}{\Theta_t} > \sigma$, then g_L is negative. Otherwise, g_L is negative if the unemployment rate is lower than a certain threshold, i.e. $u_t < \bar{u}_t$ where $\bar{u}_t = \left(2 - \frac{\eta_t}{\Theta_t \sigma}\right)^{-1}$. Thus, when the unemployment rate is high enough such that $u_t > \bar{u}_t$, g_L is unambiguously positive and so is

$g_L - h_L$. This is the only case where it is possible to determine unambiguously the impact of variables on L_t . In such a case, $\frac{dL_t}{dK_t} \Big|_{\frac{d\eta_t=0}{dN_t^y=0}} < 0$, $\frac{dL_t}{dN_t^y} \Big|_{\frac{dK_t=0}{d\eta_t=0}} > 0$ and $\frac{dL_t}{d\eta_t} \Big|_{\frac{dK_t=0}{dN_t^y=0}} < 0$. Therefore, except in this special case, $g_L - h_L$ is ambiguous. Due to the indeterminacy of g_L , I perform a quantitative analysis in section 3.

3 Quantitative analysis

There are three objectives in this quantitative analysis. Firstly, to match the labor share dynamics over the period 1970 to 2010. Secondly, to produce model predictions over the period 2010 to 2080. Finally, to decompose demographic effects on the labor share and their transmission channels. Based on analytical results, I compute quantitative predictions for France and the United-States. One period in the model corresponds to 40 years in the data. Following the methodology of [Gonzalez-Eiras and Niepelt \(2012\)](#) to simulate an OLG model, I compute four sequences of model predictions with a period length of 40 years each. Periods of the first sequence corresponds to 1970, 2010, 2050, ... ; for the second sequence to 1980, 2020, 2060, ... ; for the third sequence to 1990, 2030, 2070, ... ; for the fourth sequence to 2000, 2040, 2080, When reporting time series predictions, I list the four sequences in a single time series.

3.1 Calibration

With a period length of 40 years, agents are considered as young between their 20 to 60 years old and as elderly thereafter.¹⁸ I compute the old-age dependency ratio from the data as the number of old households divided by the number of young households (i.e. $p_t/n_t \equiv N_t^o/N_t^y$).

¹⁸An implicit assumption of the model is that retirement age is constant (this assumption is discussed in section 4). The french average effective retirement age is about 67.8 years-old in 1970 and has declined down to 59.3 in 2010. While the US one has moved from 68.4 to 65.6 over the same period (data from the [OECD Database](#)). I suppose, as an approximation, that agents retire at 60 years-old to match period lengths of the calibration. Such an assumption should not affect the voting outcome because almost-retired agents may anticipate their future situation once they vote. However, implications in terms of labor supply might be discussed. Nonetheless, 5 years approximation remains marginal compared to the 40 years between two periods.

Figure 2: Demographic variables time series

Notes: The black curves refer to France and the gray ones to the United-States.

Then, the population growth rate at time t is computed using the ratio between the number of young households in period t relative to the number of young households in the previous period of the sequence (i.e. $n_t = N_t^y / N_{t-1}^y$). Finally, the survival rate at time t is the product of the old-age-dependency ratio and the population growth.¹⁹ Figure 2 plots demographic variables for both countries.

Economic variables data (K_t , emp_t , Y_t , θ_t) are taken from the [Penn World Table 9.1](#).²⁰ When considering data on the labor share, [Gollin \(2002\)](#) shows that it is necessary to take into account self-employed income. In the model, workers are only young individuals and provide only labor supply. Therefore, I assume that self-employed people earn an income that is characterized as a compensation.²¹ I also use the government revenue in % of GDP from the [OECD database](#) as proxy for the tax rate τ_t . In the model, labor supply is inelastic and there is no distinction between unemployed and inactive households. Unemployed agents in terms of the model specification corresponds to all agents that do not work. However, in

¹⁹Demographic data from 1950 are taken from the [United Nations World Population Prospects 2017](#). Demographic data before 1950 are from <http://www.populstat.info>. Demographic data between 2010 and 2100 are the “medium variant” estimates from the United Nations. Both rates n_t and p_t converges to unity in the very long run (after the 5th period of the 4th sequence, hence 2160). However, I limit my analysis to 3 periods (hence 2080) due to high uncertainty above 100 years.

²⁰ K is the capital stock at constant 2011 national prices, emp the number of persons engaged, Y the real GDP at constant 2011 national prices and θ the share of labor compensation in GDP. K and Y are adjusted with the average annual hours worked by persons engaged. For further details the reader is referred to [Feenstra et al. \(2015\)](#).

²¹This specification corresponds to the first adjustment method of [Feenstra et al. \(2015\)](#).

Table 1: Parameters

Parameter		France	United States
ϕ	Capital share in 1970	0.27	0.325
γ	Relative bargaining power of the union	0.5	0.5
α	Discount rate	0.669	0.669
σ	Capital-labor elasticity of substitution	1.279	1.234
ω	Relative ideological spread-out	0.983	1.533
β	Preference for government health expenditure	0.739	0.138
A	Scale parameter of the production function	28.23	22.84

Note : Single-equation estimation of σ from the two first-order conditions of the profit maximization with normalized CES production function. σ estimates are significant at $p < 0.1$ for France and $p < 0.05$ for the United States. Details in [appendix C](#).

high-income countries, such as France and United States, inactive individuals also benefits from redistribution. This redistribution is captured through unemployment benefits b_t in the model. I compute the unemployment rate such that $u_t = 1 - emp_t/N_t^{15-64}$, where N_t^{15-64} is the working age population.²² Results are robust to different specifications of the unemployment rate. Then, I compute labor such that $L_t = (1 - u_t)N_t^y$. I normalize K_t and L_t to their 1970 values. As a consequence, the capital-to-labor ratio k_t is also normalized and is equal to 1 in 1970. Then, N_t^y and N_t^o are normalized such that u_t matches the data in 1970.

Once all stock variables are normalized, I calibrate the 7 parameters $\{\phi, \sigma, \gamma, \alpha, \omega, \beta, A\}$. Table 1 summarizes parameters for both countries. The first parameter ϕ corresponds to the capital share in 1970. Because the capital-to-labor ratio is normalized (i.e. $k_{1970} = 1$), the labor share θ in 1970 is equal to $1 - \phi$. The main parameter of the model is the elasticity of substitution between capital and labor σ . I estimate it using a combination of the first order conditions of the profit maximization. Details of the estimation in [appendix C](#). I obtain

²²I consider the whole working age population instead of the young population in order to compute the unemployment rate. Due to demographic specification of the model, young agents correspond to those between 20 and 60 years old. The number of persons engaged (*emp*) per age groups are not available in [PWT 9.1](#). Therefore, taking only N_t^y as denominator would bias downward the unemployment rate.

1.279 and 1.234, respectively, for France and the United States. According to the estimation, both input factors are gross substitute. These estimates are in line with [Karabarbounis and Neiman \(2014\)](#) who use cross-sectional data on 50 countries over the period 1975-2012 to find an elasticity greater than 1 and on average around 1.28 in their baseline estimates. I set the relative bargaining power of the union γ to 0.5. Hence, I assume that neither the representative union nor the representative firm have any other advantage in the bargaining apart from their respective outside options. I also set the discount rate at 0.669 according to the literature. Then, I have three remaining parameters that are deduced. The relative ideological spread-out ω is set such that the model prediction matches the capital-to-labor ratio k in 1970. The preference for government health expenditure β is set to match the tax rate τ in 1970. Finally, the scale parameter of the production function A is set with grid-search to match the average labor share between 2008 and 2012.

Due to initial labor share values, the parameter distribution ϕ which correspond to the capital share in 1970 is larger in the United States than in France. Moreover, the relative per-capita political influence of old households ω is also greater. This deduced parameter suggests that young generations have less political weight in the United States compared to France. Notice that ω is lower than one for France. It implies that French youth voting behavior is more sensitive to policy changes compared to elderly. French households have a much greater preference for government health expenditure β . Finally, the scale parameter A is ranged between 20 and 30 for both countries.

3.2 Model predictions over the period 1970-2010

3.2.1 The labor share decline

Figure 3 displays the labor share from model predictions and data over the period 1970-2010. The model reproduces the global trend of the data for both countries. For France, the model is not able to reproduce the huge decline of the labor share between 1980 and 1990. This gap may be explained by different factors not considered in the model. I modelize the workers

Figure 3: Model prediction of the labor share

Notes: The solid curve corresponds to the labor share in the data, from the [Penn World Table 9.1](#) with adjustment method 1. The dashed curve is the model prediction with a unique capital-labor elasticity of substitution. The dotted curve is the model prediction for France with a break in the regime for the capital-labor elasticity of substitution (details in [appendix D](#)).

outside option within the wage bargaining using only unemployment benefits and the tax rate. Other labor market institutions may have played a role in firms' employment policies during this period. Indeed, I consider a right-to-manage specification, meaning that the firm has the prerogative to hire and fire. In my framework, there is no firing cost. [Bentolila and Bertola \(1990\)](#) build a model with linear adjustment cost and find that firing costs have an effect on firms propensity to hire and fire. Further, they also find that firing costs slightly increase average long-run employment. Subsequent to the oil shock, firms were not able to fire as they would have due to high firing costs.²³ They reduced employment with attrition, thus the process took time and the employment remained higher than it should during some years. In addition, most of the employment security policies were introduced between the 1960s and the beginning of the 1970s. Here again, these protections may be the result of the

²³[Blanchard \(1997\)](#) also shows that wages failed to adjust to the productivity slowdown and adverse supply shocks of the 1970s. Thus, wages remained relatively high and so did the labor share. This phenomenon was more pronounced in European Continental countries than in the Anglo-Saxon countries, mainly due to labor market institutions.

baby-boomers generation operating a political pressure to secure employment. Although, I do not integrate it in the model. Then, France during the 1980s has started to implement policies in order to make the labor market more flexible. For instance, short term contracts have been introduced in 1979. To summarize, the labor market institutions in France were tremendously different before and after the 1980s. The reason why the model prediction does not reproduce the labor share from the data owes to the calibration of the model that is in line with the labor market institutions after 1980, but not before. Another way to think about it, in terms of the model, is to suppose that the capital-labor elasticity of substitution was much smaller before 1980.²⁴ Therefore, the representative firm was constrained and not able to substitute labor by capital as much as the model predicts. In line with the above arguments, I investigate whether there is a change in the regime of σ over this period. Details of the methodology in [appendix D](#). I find that such a break has occurred during the 1980s in France. The dotted curve is the model prediction with a capital-labor elasticity of substitution of 1 in 1970-1980 and about 1.321 thereafter. The scale parameter A is also changed to 23.891 for France. For the United States, the model tends to overestimate the labor share in 1980 and 1990 and underestimate it in 2000. However, model predictions capture the global trend of the labor share over the period. To highlight the mechanisms of this decline, it is necessary to look at the variations of determinant variables.

3.2.2 Mechanisms of the decline

The state of the economy is determined by the interaction of the wage bargaining and the voting. Both processes take place simultaneously. The demographic context over this period, as presented in [figure 2](#), is such as the population growth n_t slightly exceeds the increasing survival rate p_t . Thus, the old-age-dependency p_t/n_t remains relatively constant between 1970 and 2000. With a decline in France in 1980 due to the massive entry of the baby-boomers in the labor force. Finally, the old-age-dependency ratio starts to increase between

²⁴Perhaps even lower than 1, meaning that an increase in k_t leads to an increase in θ_t .

Figure 4: Deviation from the 1970 steady-state of public policy variables

Notes: The unemp. benefits share corresponds to the share of the unemployment benefits in the government spending, i.e. $buN^y/(\tau Y)$. The black curves refer to France and the gray ones to the United-States. The solid curves refer to the model predictions with a unique capital-labor elasticity of substitution and the dashed ones to the model prediction for France with a break in the regime for the capital-labor elasticity of substitution.

2000 and 2010 due to a steady population growth but a sharply increasing survival rate. This increase is also due to the baby-boomers' cohort who begins to retire. As a result of this demographic context, the youth political weight η_t was above its 1970's level until 2000 in both countries.

Figure 4 displays the deviation from the 1970 steady-state of public policy variables in percentage. As the youth political weight raises and because they desire more redistribution, the tax rate τ_t increases (i.e. $\partial\tau_t/\partial\eta_t > 0$). Due to the opportunistic behavior of political parties, pro-youth policies are implemented. In the model, pro-youth policies correspond to pro-labor policies and are translated in terms of unemployment benefits in order to insure the unemployment risk. Thus, the unemployment benefits share in government revenue b share increases at the cost of the government health spending share in government revenue.

These policy changes interact with the wage bargaining because they affect the outside option of the young agents. Figure 5 displays the deviation from the 1970 steady-state of wage bargaining variables in percentage. Pro-youth public policies motivated by a higher youth political weight leads to an increase of the unemployment benefits and a decline of the disposable income rate $(1 - \tau_t)$. These two variables determine the outside option $b_t/(1 - \tau_t)$

Figure 5: Deviation from the 1970 steady-state of wage bargaining variables

Notes: The outside option corresponds to $b/(1 - \tau)$. The reader is referred to the footnote of the figure 4 for the legend of the curves.

Figure 6: Deviation from the 1970 steady-state of production function variables

Notes: The reader is referred to the footnote of the figure 4 for the legend of the curves.

within the wage bargaining. The decrease of the denominator exceeds the increase of the numerator. Thus, the net effect on the outside option is positive and allows workers to bargain a greater wage w_t . The gain in net wage $(1 - \tau_t)w_t$ exceeds the one in unemployment benefits per capita b_t . Hence, employment is even more worth as unemployment in terms of utility (i.e. $dX_t > 0$).

Due to the ability of workers to bargain a greater wage, the representative firm shifts away from labor. Figure 6 displays the deviation from the 1970 steady-state of production function variables in percentage. This behavior is permitted by two features of the model. First, the right-to-manage specification of the wage bargaining enables the firm to hire and

Figure 7: Deviation from the 1970 steady-state of unemployment's component variables

Notes: The reader is referred to the footnote of the figure 4 for the legend of the curves.

fire as much as wanted. Second, the capital-labor elasticity of substitution σ is greater than unity for both countries. Thus, both input factors are gross substitute. The firm is able to substitute labor with capital for a given output level. This behavior leads to a decline of the number of worker L_t because the labor cost (i.e. the wage) has increased. Notice that the substitution effect is more vigorous in France because of the relatively higher elasticity of substitution σ . French firms are able to substitute relatively more labor with capital and also have a faster growth in capital stock K_t . Thus, the number of workers becomes lower than its 1970's level in France. While the United-States manage to slightly increase its labor factor. As a consequence, the US production Y_t grows faster.

The slowdown in employment has consequences on the labor market. Figure 7 displays the deviation from the 1970 steady-state of unemployment's component variables in percentage. This slowdown in employment directly raises unemployment in France by reducing the number of workers. Furthermore, the effect is all the more tremendous because the labor force N_t^y grows due to the baby-boomers' arrival. The United-States also know a growing population but the impact on unemployment is much weaker due to the increasing number of workers, as discussed above.

The dynamics of the production function affects the determinants of the labor share. Figure 8 displays the deviation from the 1970 steady-state of labor share's component variables

Figure 8: Deviation from the 1970 steady-state of labor share's component variables

Notes: The reader is referred to the footnote of the figure 4 for the legend of the curves.

in percentage. Due to the fact that both input factors are gross substitute, the output-per-worker Y_t/L_t increases when the capital-per-worker k_t does so. This increase exceeds the one of the wage. As a result, the labor share declines.

Let summarize the mechanisms over this period. The youth fosters a pro-labor public policy due to a relatively high political weight. This institutional design raises the outside option of the workers. It gives more bargaining power to the union who is able to bargain greater wages. The cost of labor becoming too high, the firms decide to shift away from labor. The fact that both input factors are gross-substitute allows firms to substitute labor with capital. The shift-away from labor engenders an increase of the output-per-worker which thwarts and exceeds the wage gain. Thus, the labor share declines. Moreover, unemployment rises due to a growing labor force.

3.3 Model predictions over the period 2010-2080

3.3.1 The labor share resurgence

Figure 9 displays the model predicted labor share over the period 1970-2080. The model predicts that the labor share should continue to decline during the next decades in both countries. However, France should face a slight rise in 2020 up to 65.9 % before to shrink

Figure 9: Model prediction of the labor share

Notes: The reader is referred to the footnote of the figure 3 for the legend of the curves.

again.²⁵ While the US labor share should remain stable around 62.6 % between 2010 and 2040 and then follow the same pattern.

3.3.2 Mechanisms of the resurgence

The demographic context over the period 2010-2080, as presented in figure 2, is roughly the same for France and the United-States. The population growth n_t faces a sharp decline between 2010 and 2050 before to stabilize thereafter. Meanwhile, the survival rate p_t grows around 4% per decades on average. Thus, the old-age-dependency ratio skyrockets until 2050. Once the population growth becomes stable, the ratio still grows but at a lower rate. This important aging of the population is mainly due to the baby-boomers' retirement. As a result of this demographic context, the youth political weight η_t never gets back to its 2010's level and will strongly decline until 2050 for both countries.

Figure 10 displays the deviation from the 1970 steady-state of public policy variables in

²⁵Under the model specification with a break in the regime of σ for France (i.e. the dotted curve), the peak occurs in 2030 with a labor share up to 66.1 %.

Figure 10: Deviation from the 2010 steady-state of public policy variables

Notes: The unemp. benefits share corresponds to the share of the unemployment benefits in the government spending, i.e. $buN^y/(\tau Y)$. The reader is referred to the footnote of the figure 4 for the legend of the curves.

percentage. The young political weight η_t sharply declines due to the aging of the population. Thus, opportunist political candidates favor old households who desire less redistribution (i.e. $\partial\tau_t/\partial\eta_t > 0$). Pro-elderly public policies are implemented. In terms of the model, it is translated by an increase of the health spending share in government revenue at the cost of the unemployment benefits one b share.

These policy changes interact with the wage bargaining because they affect the outside option of young households. Figure 11 displays the deviation from the 2010 steady-state of wage bargaining variables in percentage. Pro-elderly public policies leads to slightly weaken

Figure 11: Deviation from the 2010 steady-state of wage bargaining variables

Notes: The outside option corresponds to $b/(1 - \tau)$. The reader is referred to the footnote of the figure 4 for the legend of the curves.

Figure 12: Deviation from the 1970 steady-state of production function variables

Notes: The reader is referred to the footnote of the figure 4 for the legend of the curves.

the outside option $b_t/(1-\tau_t)$ within the wage bargaining for both countries between 2010 and 2050. Workers are no longer in position to bargain greater wages and have to concede a wage cut. Hence, having a job between 2010 and 2050 is less worth in terms of utility as it was worth in 2010. But the drawback is not that tough because the declining wage goes along with a decline of the tax rate. In both countries, the outside option rises over the period 2050-2080 and so does the bargained wage. This increase is mainly due to the disappearance of baby-boomers. Thus, the age-related conflict within the public policy becomes relatively more in favor of the youth again.

Figure 12 displays the deviation from the 2010 steady-state of production function variables in percentage. As the wage decreases between 2010 and 2050, the representative firm has incentive to hire. Thus, the labor L_t does increase over this period. Meanwhile, the capital stock K_t has increased due to savings S_t of the previous periods. Thus, both input factors increase and so does the production Y_t . After 2050, France and the United-States diverge in their trajectories. On one hand, the US capital stock rises due to high savings of the previous periods.²⁶ This rise is strong enough to foster the representative firm to hire workers. Thus, the substitution mechanism does not undertake. On the other hand, the

²⁶This increase in savings owes to the baby-boomers cohort when they were young. Their massive entry on the labor market, rising expected life expectancy and higher wages have fostered savings and therefore the capital available in the economy once old.

Figure 13: Deviation from the 2010 steady-state of unemployment's component variables

Notes: The reader is referred to the footnote of the figure 4 for the legend of the curves.

increase of the French capital stock does not follow the same exploding pattern. The french representative firm, as during the end of the twentieth century, shifts away from labor and decreases the number of workers. This divergence also appears on the labor market.

Figure 13 displays the deviation from the 2010 steady-state of unemployment's component variables in percentage. The labor force N_t^y is roughly constant over the whole period and France is even below its 2010's level. Thus, the number of workers variations L_t mainly drives the unemployment ones. The unemployment rate decreases in the United-States over the whole period. It falls down to 1.69% by 2080 against 44.6% in 2010. Here again, the sharp increase of the capital stock fosters employment until almost full-employment. The french unemployment rate decreases until 2050 before to slightly rise a bit and stabilize itself around 26.9% in 2080.

Figure 14 displays the deviation from the 2010 steady-state of labor share's component variables in percentage. French and US workers experience a minor reduction of their wage w_t between 2010 and 2050 and so does the output-per-worker Y_t/L_t . The latter being greater than the former, the French labor share slightly increases. The US labor share remains constant because both variations compensate. After 2050, both labor shares decline to reach 62% and 59.8%, respectively for France and the United-States. While their respective levels in 2010 were 65.1% and 62.5%.

Figure 14: Deviation from the 2010 steady-state of labor share's component variables

Notes: The reader is referred to the footnote of the figure 4 for the legend of the curves.

3.4 Counterfactual and aging effect decomposition

So far, I have highlighted the different mechanisms through which the age structure of the population affects economic variables and therefore the labor share. For the remaining part of the paper, I consider that the previous model prediction is the benchmark prediction. For the french case, I envisage the model specification with a break in the regime of σ . To summarize, demographic changes are due to two determinant variables in the model : the population growth n_t and the survival rate p_t . These variations may affect the labor share through two channels : the direct cohort effect n_t, p_t, p_{t+1} and the indirect cohort effect $\eta_t(n_t, p_t, p_{t+1})$.

I make counterfactual predictions in order to quantify the respective role of each determinants and channels. The principle is to neutralize either a determinant of the demographic change or a channel through which the labor share is affected. The intuition behind the counterfactual is to observe what would have happened in terms of model predictions if this effect/channel was neutralized. By comparing a counterfactual simulation to the benchmark one, I can quantify its extent. I proceed in two steps. First, I examine the impact of the different determinants of demographic changes (i.e. n_t versus p_t). Second, I investigate through which channels it occurs (i.e. direct versus indirect).

Table 2: Demographic variables in 1970

	Variable	France	United-States
p_{1970}	Survival rate in 1970	0.417	0.476
n_{1970}	Population growth in 1970	1.134	1.597
p_{2010}	Expected survival rate in 2010	0.583	0.561
$\frac{p_{1970}}{n_{1970}}$	Old-age-dependency ratio in 1970	0.368	0.298
η_{1970}	Youth political weight in 1970	3.846	3.008

3.4.1 Survival rate and population growth effects

To neutralize the impact of the survival rate p_t , I assume that it remains at its 1970's level. Thus, $p_t = p_{1970}$ and $p_{t+1} = p_{2010}$. Old household population size is recalculated such that $N_t^{o'} = N_t^o \times \frac{p_{1970}}{p_t}$. Moreover, $\eta_t = \frac{n_t}{p_{1970}} \frac{1+\alpha p_{2010}}{\omega}$. The other demographic variables (i.e. n_t and N_t^y) follow the time series of the benchmark simulation. The initial capital stocks of the four sequences are also recalculated such that $K'_0 = \frac{1+\alpha p_t}{p_t} \frac{p_{1970}}{1+\alpha p_{1970}} K_0$.²⁷ The methodology is analogous to neutralize the impact of the population growth but with $n_t = n_{1970}$, $N_t^{y'} = N_t^y \times \frac{n_{1970}}{n_t}$ and $\eta_t = \frac{n_{1970}}{p_t} \frac{1+\alpha p_{t+1}}{\omega}$.²⁸ Finally, a last counterfactual is made to neutralize both effects. So, $p_t = p_{1970}$, $p_{t+1} = p_{2010}$, $n_t = n_{1970}$ and $\eta_t = \eta_{1970}$. As before, population sizes and initial capital stock values are recalculated. Here, the old-age-dependency ratio remains constant. Table 2 summarizes demographic variables in 1970.

Figure 15 displays the model predictions of the labor share with counterfactual specifications. To interpret the role played by each demographic variable, I compare each counterfactual time series to the benchmark one. For instance, let start with the impact of the survival rate in France. I look at the dashed curve with respect to the solid one. This curve

²⁷Setting constant the survival rate implies changes in the saving rate through the expected survival rate p_{t+1} . $K_0 \equiv S_{-1} = \frac{\alpha p_0}{1+\alpha p_0} [(1-\tau_{-1})w_{-1}(1-u_{-1}) + b_{-1}u_{-1}] N_{-1}^y$. In order to assess the true impact of the survival rate, it is also necessary to consider saving rate changes in the counterfactual simulation. Thus, the initial capital stocks for the first periods of the four sequences becomes $K'_0 = \frac{1+\alpha p_t}{p_t} \frac{p_{1970}}{1+\alpha p_{1970}} K_0$. Notice that a change in the survival rate p_0 should also affect the aggregated disposable income of young households in $t = -1$, i.e. $(1-\tau_{-1})w_{-1}(1-u_{-1}) + b_{-1}u_{-1}$. However, I do not consider this source of change. Notice also that the term N_{-1}^y does not change because $N_{-1}^y = \frac{N_0^o}{p_0} = \frac{N_0^{o'}}{p_{1970}}$.

²⁸In this specification, the initial capital stocks are not changed because n_0 does not affect S_{-1} .

Figure 15: Model predictions of the labor share with counterfactual specifications

corresponds to the counterfactual where the survival rate p_t and p_{t+1} remain at their 1970's levels. So, if the survival rate would have not changed, then the labor share would have followed the dashed curve pattern. The dashed curve lies below the solid one. Therefore, the survival rate dynamic has a positive impact on the labor share in both countries. The way to interpret the other counterfactuals is similar. The dash-dotted curve remains above the solid one until 2050 for France and 2030 for the United States. Until these years, the population growth dynamic has a negative impact on the labor share and a positive one thereafter. Finally, the dotted curve which corresponds to the counterfactual where both effects are neutralized is below the benchmark simulation. Since 1970, all demographic dynamics have led to increase the labor share with respect to what it would have been without these dynamics. However, this representation is tediously legible. Therefore, I compute the distance between the benchmark labor share and each counterfactual labor share. Using the Chasles' relation within an affine space at each point in time, it is possible to isolate the extent of each effect.²⁹ Figure 16 displays the labor share's gap between the benchmark

²⁹Let r (resp. b, g, p) be the labor share from the red (resp. blue, green, purple) curve on figure 15. For a given year, $2\vec{r\vec{p}} = \vec{r\vec{b}} + \vec{b\vec{p}} + \vec{r\vec{g}} + \vec{g\vec{p}} \Leftrightarrow \vec{r\vec{p}} = \vec{r\vec{b}} + \vec{r\vec{g}} + \text{int.}$, where $\text{int.} \equiv \vec{b\vec{p}} + \vec{g\vec{p}} - \vec{r\vec{p}} = \vec{g\vec{p}} + \vec{b\vec{r}} = \vec{b\vec{p}} + \vec{g\vec{r}}$ is the interaction of both effects defined as the part which is not exclusively explained by both effects independently.

Figure 16: Aging-effect decomposition by determinants

and the counterfactuals in percentage points. As mentioned above, the survival rate effect has kept the labor share relatively high in both countries. Another way to think about that is to consider demographic dynamics in terms of cohort sizes. Until 2010, if the survival rate had been held constant, then the massive increase in the population of young households due to the baby-boomers' presence would have generated an even larger decline of the labor share. However, the aging population (i.e. the increase of the survival rate) has thwarted part of this fall. Notice that the difference with the counterfactual is less than 1% in the case of the United-States. It suggests that the aging phenomenon over this period is a larger determinant of the labor share in France compared to the United-States. The analysis of the determinants only reveals part of the explanation. It is also necessary to look at the channels that affect the labor share.

3.4.2 Direct and indirect cohort effects

To neutralize the indirect cohort effect, I fix the youth political weight η_t to its 1970's value but I keep the demographic variables' time series n_t , p_t and p_{t+1} as in the benchmark

Figure 17: Model predictions of the labor share with counterfactual specifications

simulation. Thus, $\eta_t = \eta_{1970}$. To neutralize the direct cohort effect, I assume that all the demographic variables remain at their 1970's level. Thus, $p_t = p_{1970}$, $p_{t+1} = p_{2010}$, $n_t = n_{1970}$ and population sizes but also initial capital stocks are recalculated. But the youth political weight time series η_t is the one of the benchmark simulation. Finally, a last counterfactual is made where I neutralize both effects.³⁰

Figure 17 displays the model predictions of the labor share with counterfactual specifications. The methodology to interpret this figure is similar to the one of the figure ???. The dash-dotted curve corresponds to the direct cohort effect. For both countries, this curve is below the benchmark curve until 2010 and above thereafter. It means that the demographic dynamics' net impact through the direct channel is positive on the labor share until 2010 and negative thereafter. Looking at the dashed curve, it is slightly above before 2000 and largely below thereafter. The net impact of the indirect cohort effect is negative up to 2000 and positive subsequently. However, this representation is also tediously legible. Therefore, I isolate the extent of each channel with the same methodology as before. Figure 18 displays the

³⁰This last specification is the same as in the survival rate and population growth effects decomposition. So the purple curve in figure 15.

Figure 18: Aging-effect decomposition by channels

labor share's gap between the benchmark and the counterfactuals in percentage points. The direct cohort effect is positive when the baby-boomers are young and after becomes negative. While the indirect cohort effect has the opposite pattern. The direct cohort effect dominates the indirect one until 2010 before to become less influential. Until 2010, if the demographic variables had been held constant, then the relatively high political power of the youth due to the baby-boomers' presence would have generated an even larger decline of the labor share. However, the aging population was mainly driven by the increasing survival rate which has thwarted part of the fall. Notice that, here again, the difference with counterfactual is less than 1% in the case of the United-States. It suggests that the aging phenomenon over this period is a larger determinant of the labor share in France compared to the United-States. After 2010, so once the baby-boomers' cohort retires, the model predicts that the indirect cohort effect (i.e. the decline of the youth political power) should exceed the direct one. This is directly related to the mechanism analysis of section 3.2. The baby-boomers and more generally the old households becomes the winners of the age-related conflict within the public policy over this period. Thereby, they reduce the workers' outside option which

Figure 19: Aging-effect decomposition by periods and countries

leads to a wage cut or more precisely to a wage stagnation. The labor cost remains constant while the capital available in the economy accumulates. It generates an incentive for the representative firm to hire more workers. As a result, the labor share increases.

3.4.3 Summary

Figure 19 summarizes the aging-effect decomposition by periods and countries. Both countries have almost similar patterns. The main determinant of the aging phenomenon is the survival rate. On average, it explains 54.5% for France and 78.1% for the United-States of the impact on the labor share over the period 1980-2010. This decomposition persists thereafter. However, the channel decomposition does not. Between 1980 and 2010, demographic dynamics affect the labor share mainly through the direct channel in France. While the indirect one is dominant in the United-States. On average, the share explained by the direct cohort effect is about 53.1% for France and 38.2% for the United-States. However, over the next period, the direct cohort effect is not the dominant channel anymore in France. It falls down to 20.3%. It suggests that the indirect cohort effect becomes the main carrier

of the demographic dynamics on the labor share. While it remains relatively stable in the United-States around 35.7%.

4 Discussion

4.1 Age-related conflict : who are the winners ?

So far, the labor share has been declining due to the baby-boomers generation in both countries. First, when they were young because they shaped the public policy and so the labor market institutions in their favor. The firms answered to that by substituting labor to capital. Second, when they were old because they have considerably increased the available capital in the economy through savings allowing the firms to substitute even more. However, the labor income share is a gross indicator of inequalities. A more appropriate indicator may be the income ratio between young and old after redistribution.

From equation (14), I have that the after-tax young-to-old income ratio is equal to the young political weight (i.e. $Y_t^y/Y_t^o = \eta_t$). While the before-tax young-to-old income ratio corresponds to the labor-to-capital ratio (i.e. $\Theta_t = \frac{w_t L_t}{r_t K_t}$). Figure 20 displays these income ratios in deviation from the 1970 steady-state. While the labor share and so the labor-to-capital ratio (i.e. before-tax young-to-old income ratio) sharply decline between 1970 and 2000, the after-tax young-to-old income ratio lies over its 1970's level during the same period. Even if I include the government health spending as part of the old households income, the young-to-old income ratio remains over its initial level until 2000.³¹ This model prediction holds for both countries. The baby-boomers gross income share (i.e. labor income share) has declined due to the mechanisms previously mentioned when they were young. However, they also have spurred political parties to implement redistributive public policies.³² This redistribution is characterized, in terms of the model, through a raise of the tax rate and an

³¹In terms of deviation, the curve is combined with the dashed one.

³²This is the result of the probabilistic voting specification. The opportunist behavior of political parties lead them to favor this generation in order to maximize their probability to win the election.

Figure 20: Deviation from the 1970 steady-state of the before-tax and after-tax young-to-old income ratios

The solid curve corresponds to the before-tax young-to-old income Θ_t ratio also named the labor-to-capital income ratio $\frac{w_t L_t}{r_t K_t}$ and the dashed curve is the after-tax young-to-old income ratio Y_t^y/Y_t^o which is equal to the youth political power η_t . Deviation is expressed in percentage.

increase of the unemployment spending share within the government revenue.³³ Thus, they have been able to seize part of their elders income through redistribution. Even though baby-boomers appeared has income losers over this period because the labor share was falling, they are actually the winners once net income is considered.

Another way to determine the winners of the age-related conflict within the public policy is to look how the GDP is allocated in the economy. Figure 21 displays the income allocation after redistribution. The dashed curve corresponds to the labor share, so the before-tax young income share. As long as this curve lies in the area of the government unemployment spending share, it means that old agents fund unemployment spending through their taxes. On the contrary, when the dashed curve lies in the area of the government health spending share, the young agents fund government health spending for their elders. The US share of GDP which is allocated to health spending is quite small compared to the French one.

³³Notice that the increase of the unemployment spending share is driven and accentuated by the raising unemployment due to factor substitution.

Figure 21: After-tax income share allocation

This is directly related to the preference parameter for government health spending β .³⁴ The US young generations are the winners of the age-related conflict from 1970 to 2020 which corresponds to the active period of the baby-boomers. Once the US population ages and therefore the baby-boomers, old households dominates the public policy conflict. However, the size of the government revenue declines due to the fact that the United-States converges to full employment in the long run. For France, the baby-boomers also dominate the public policy conflict between 1990 and 2010 when they are active. Once they retire, so over the period 2010-2040, they are still the winners of this conflict and their children fund government health spending. Notice that the size of the welfare state corresponds to the sum of the unemployment benefits share in GDP and the health spending share in GDP.

4.2 Retirement age

So far, I have not discussed the retirement age and its implications on the labor share. As mentioned in the introduction, the relationship between aging and economic growth

³⁴ $\beta_{FR} = 0.739$ and $\beta_{US} = 0.138$.

has received much more attention than the one with the labor share. [Gonzalez-Eiras and Niepelt \(2012\)](#) predict that the retirement age in OECD countries should increase in response to population aging. In their model of politico-economic equilibrium, individuals vote with perfect foresight and decide to raise retirement age as long as population ages. Agents work longer and so accumulate more wealth, it reduces social-security transfers and thereby releases more government spending to public investment which is an engine for growth.³⁵ On the contrary, [Futagami and Nakajima \(2001\)](#) claim that population aging does not necessarily depress economic growth and may even foster it through savings. Thus, postponing the retirement age would result in a decline of savings and so the economic growth. [Dedry et al. \(2017\)](#) also discuss the role of legal retirement age according to the type of pension system in a context of population aging due to either declining fertility or increasing longevity.

In order to take into account the role of retirement age, I perform counterfactual predictions with different scenarii based on an exogenous change. The retirement age is captured within the variable p_t which depends negatively on it but positively on the life expectancy. I do not endogenize this variable due to the limited form of rationality and to the several assumptions that would be required.³⁶ In the public debate, it is often argued that the legal retirement age should change in the future, usually upward, as claimed by [Gonzalez-Eiras and Niepelt \(2012\)](#). Between 2020 and 2030, I suppose a positive exogenous shock on the age of retirement. Meaning that less individuals would reach the old age which is translated into a decline of the survival rate, i.e. p_t . As in section 3.4, other demographic variables have

³⁵However, this result contrasts with [Jäger and Schmidt \(2016\)](#) who find out that the share of elderly people and public investment are negatively co-integrated. They use panel data of 19 OECD countries from 1971 to 2007. This gap may be due to two reasons: *i*) some public policy instruments which are not considered in the model of [Gonzalez-Eiras and Niepelt \(2012\)](#) might invert the relationship between aging and public investment; *ii*) the perfect foresight assumption might be too strong. Both potential explanations may reconcile these diverging results.

³⁶To have an endogenous retirement age, agents should vote on it and thereby vote on the survival rate. The first question would be to determine whether agents vote on p_t , p_{t+1} or both. Then, the perfect annuity market would have a lot of implications on the results. Since savings of young agents who die before reaching old age are distributed among their surviving peers, it means that an agent has an incentive to vote for a decline of the survival rate because fewer peers would reach old age. Thus, it would increase its income and so its utility. Therefore, it would be necessary to determine whether or not agents internalize the perfect annuity market in their voting decisions.

to be changed for the period following the shock of each simulation's sequence (i.e. 2030, 2040, 2050 and 2060). However, the implications for demographic dynamics are not identical to this previous exercise. Because the greater the retirement age, the longer an individual remains young in terms of the model. Thus, these individuals do not vanish but just remain longer in the labor force.³⁷ Therefore, conjointly with the decline of the survival rate, there is a share of the young population that does remain young. From the identity $\frac{N_t^o}{N_t^y} \equiv \frac{p_t}{n_t}$, I obtain:

$$\frac{\dot{N}_t^o}{N_t^o} - \frac{\dot{N}_t^y}{N_t^y} = \frac{\dot{p}_t}{p_t} - \frac{\dot{n}_t}{n_t} \quad (18)$$

where the upper dotted variables correspond to the variables' variation, e.g. $\dot{N}_t^o = N_t^{o'} - N_t^o$ where $N_t^{o'}$ is the new value for N_t^o . This equation has to be satisfied. The exogenous shock on p_t affects all other demographic variables. Firstly, the size of the old population varies as much as the survival rate does, i.e. $\frac{\dot{N}_t^o}{N_t^o} = \frac{\dot{p}_t}{p_t}$. Secondly, the variations of the young population's size are inversely proportional to the ones of the old population size, i.e. $\frac{\dot{N}_t^y}{N_t^y} = -\frac{\dot{N}_t^o}{N_t^o}$. Thirdly, by taking into account the two previous points and the fact that equation (18) has to be satisfied, it implies that $\frac{\dot{n}_t}{n_t} = -\frac{\dot{p}_t}{p_t}$. Therefore, the exogenous shock on p_t affects the other variables with the same magnitude. Hence,

$$\begin{aligned} \dot{N}_t^o = \frac{\dot{p}_t}{p_t} N_t^o &\implies N_t^{o'} = \left(1 + \frac{\dot{p}_t}{p_t}\right) N_t^o \\ \dot{N}_t^y = -\frac{\dot{p}_t}{p_t} N_t^y &\implies N_t^{y'} = \left(1 - \frac{\dot{p}_t}{p_t}\right) N_t^y \\ \dot{n}_t = -\frac{\dot{p}_t}{p_t} n_t &\implies n_t' = \left(1 - \frac{\dot{p}_t}{p_t}\right) n_t \end{aligned}$$

where $\frac{\dot{p}_t}{p_t} = \frac{p_t' - p_t}{p_t} \implies p_t' = p_t + \dot{p}_t$. Thus, the new demographics variables $N_t^{o'}, N_t^{y'}, p_t', n_t'$ are computed for the years 2030, 2040, 2050 and 2060. For the years 2070 and 2080: n_t' follows the benchmark time series and population sizes are computed with $N_t^{o'} = p_t' N_{t-1}^{y'}$ and $N_t^{y'} = n_t' N_{t-1}^{o'}$. Notice that new values of the expected survival rate p_{t+1}' changes according

³⁷In the same way, the capital stock of these periods is not changed as in section 3.4 because it has already been accumulated through savings from previous periods. It has no reason to vanish or to be scraped.

to p'_t . Moreover, $\eta'_t = \frac{n'_t}{p'_t} \frac{1+\alpha p'_{t+1}}{\omega}$ is also recomputed.

Two types of scenario are possible for a change in the age of retirement between 2020 and 2030. Firstly, I consider that the retirement age increases in such a way that the survival rate is negatively affected by 10% in 2030.³⁸ Thereafter, the survival rate grows at the same growth rate as in the benchmark simulation.³⁹ This first scenario can be summarized as a one-shot shift by 10% of the survival rate. Secondly, another scenario is to consider that retirement age increases in such a way that the survival rate grows at a fraction $\zeta \in [0, 1]$ of the benchmark simulation's growth rate. The new values of the survival rate p'_t after 2030 are described as follow:

$$p'_t = \zeta(p_t - \bar{p}) + \bar{p}$$

where \bar{p} is the value of the survival rate in 2030. This can be interpreted as a gradual increase of the retirement age that is proportional to improvement in life expectancy.⁴⁰ Such dynamics imply perfect forecasts on life expectancy which are assumed in this model.

Figure 22 displays the survival rate dynamics with changing retirement age specifications for both countries. The dashed curves correspond to the first scenario mentioned above where the survival rate is shocked by -10% in 2030 and keeps its growth rate thereafter. The dash-dotted and dotted curves are two special cases of the second scenario. The dashed-dotted curves refers to the case where $\zeta = 0$, so the survival rate remains constant after 2030. It means that variations in retirement age are fully proportional to those in life expectancy. While the dotted curves coincide to the case where $\zeta = .5$. Thus, the survival rate p_t grows

³⁸The underlying (strong) assumption of this whole exercise is that the change in retirement age has no consequences on life expectancy. Some authors argue that increasing the retirement age has a negative impact on health and so the life expectancy (see, for example, [Insler 2014](#) for the United-States; [Coe and Zamarro 2011](#) for Europe). Thereby, the negative effect on the survival rate may be all the more tenacious due to the declining life expectancy. Despite the presence of a potential co-integration of the retirement age and the life expectancy, I believe that the qualitative impact is not affected in the sense that the simulation is a lower bound.

³⁹I assume that the shock does not change the future growth path of the survival rate.

⁴⁰When $\zeta = 1$, the survival rate dynamic corresponds to the one of the benchmark simulation, i.e. $p'_t = p_t$. Thus, variations are no longer proportional to changes in life expectancy. While when $\zeta = 0$, the survival rate remains constant, i.e. $p'_t = \bar{p}$ after 2030. In such a case, variations in retirement age are fully proportional to the ones in life expectancy.

Figure 22: Survival rate dynamics with changing retirement age specifications

at half of the speed of the benchmark simulation.

Figure 23 displays model predictions of the labor share according to the scenario. The raise of the age of retirement in France leads to a decline of the labor share with respect to the benchmark simulation in a first phase. In a second phase, the very long-run, the labor share is relatively greater than in the benchmark case. This result holds regardless of the scenario. In the United-States, the impact on the labor share depends on the scenario. As in France, the -10% shift scenario generates a sharper decline of the labor share before to exceed the benchmark simulation's one in the very long-run. However, both scenarii of diminished growth of the survival rate have roughly the same pattern of the benchmark labor share. But there are still above the labor share in the very long-run. Therefore, changing the retirement age may have different impact on the labor share according to the country.

The underlying mechanisms are related to those detailed in section 3. However, there is a particularity to this change of the retirement age. The capital stock does not immediately adjust in the model. Because it has been determined by the savings of the previous period of each sequence, where the expected survival rate p_{t+1} was much greater than the after-

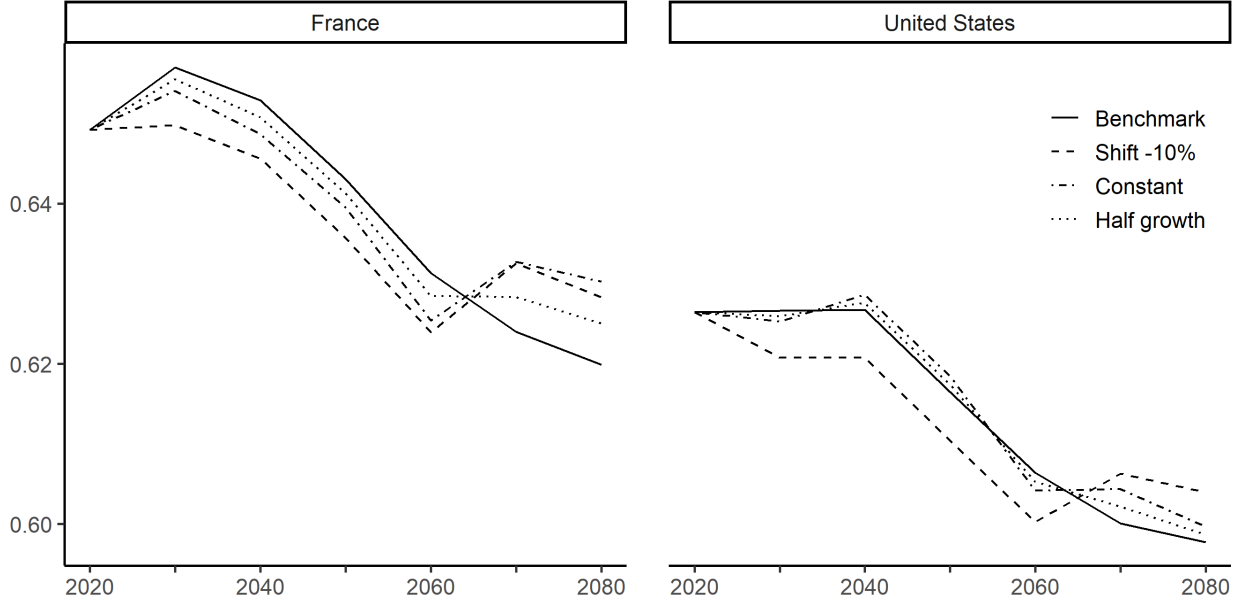

Figure 23: Model predictions of the labor share with changing retirement age specifications

reform one p'_{t+1} . This specificity cancels part of the direct cohort effect. This relatively high amount of available capital stock plays in favor of the firm within the wage bargaining. Because the firm is all the more able to substitute labor with capital. On the indirect cohort effect's side, the agents remain young longer due to the increase of the retirement age. This is translated in terms of the model with a decrease of the number of old households and an increase of the number of young households. Thus, the youth has more political weight than in the benchmark case. With this political strength, they raise their outside option through pro-young public policies which allows them to bargain greater wages. As a response, the firm shift away from labor and hire relatively less workers than in the benchmark case. As mentioned above, the relatively high amount of available capital stock due to the *stickiness* enables the firm to substitute all the more.

5 Conclusion

The literature on the labor share has emphasized the role of many factors such as the biased technical change or the labor market institutions. I built an OLG model in which labor

market institutions are endogenously determined through public policy and affect the wage bargaining. Using this model, I analyze the impact of demographic dynamics on labor share's long-term dynamics in France and the United-States. The simulation is able to replicate data for both countries since the 1970s.

Model predictions suggest that the decline of the labor share during the last decades was driven by cohort-size effects. For France, the baby-boomers cohort seems to drive the public policy and thus the way in which national income is allocated between labor and capital. When the baby-boomers cohort enters on the labor market, they shape the labor market institutions in their favor because they face an unemployment risk. Opportunistic political candidates implements public policy desired by this cohort. Thus, these more protective labor market institutions rise workers' outside option which enables unions to bargain greater wages. As a response, firms shift away from labor and use more capital. This mechanism is due to the fact that both input factors are gross substitute and that the firms have the prerogative to hire and fire. The unemployment rate rises and so does the production-per-worker. The increase of the production-per-worker offsets the one of the wage rate. Therefore, the labor share declines over the end of the twentieth century. Thereafter, the baby-boomers retire and trigger the opposite mechanism. Although the public policy shrinks the outside option of workers within the wage bargaining which should reduce wages and raise employment. The capital stock has sharply increased due to massive savings of the baby-boomers when they were young. The important available capital stock partially thwart the reverse mechanism and the labor share does not recover its past level. The model predicts a slight resurgence of the labor share for the next decades in France and a stagnation in the United-States.

Model predictions suggest that the survival rate dynamics have a larger impact on the labor share than the population growth dynamics. I also decompose this impact between two channels: the direct cohort-size effect and the indirect cohort-size effect. The former dominates for France when the baby boomers are young, while the latter takes the lead once

this cohort retires. Although the labor share declined due to public policies implemented by baby boomers, their after-tax income did not. Because they also increased the redistribution through taxes. An increase of the retirement age should decrease the labor share in the following decades due to the over-accumulation of capital and the raising political power of the youth. However, the labor share is expected to be greater in the very long-run.

The two main hypothesis of the paper are about the elasticity of substitution between capital and labor and the right-to-manage specification for the wage bargaining. Recent estimates suggest that this elasticity may be greater than one (see [Karabarbounis and Neiman 2014](#)) but an other part of the literature has found it below one, particularly for the United-States (see, for example, [Antràs 2004](#); [Chirinko 2008](#)). Moreover, I do not include any form of biased technical change within the model. This is voluntary in order to develop an other theory on the labor share's decline based on demographic dynamics. It could be the case that biased technical change is also driven by demographic dynamics through the *grabability* of workers to seize part of the rent. This grabability may be generated by some cohorts which are sufficiently numerous to shape labor market institutions in their favor and therefore in favor of labor. I let the investigation of a potential endogenous biased technical change induced by demographic dynamics for further research.

Appendix A. Uniqueness of the equilibrium

Let define, respectively, equations (16) and (17) with the functions $g(k_t, N_t^y, K_t, \eta_t; \phi, \sigma)$ and $h(k_t; \gamma, \phi, \sigma)$ such as:

$$g(k_t, N_t^y, K_t, \eta_t; \phi, \sigma) = \ln \left(\frac{\frac{N_t^y}{K_t} k_t - 1}{\frac{\phi}{1-\phi} k_t^{\frac{\sigma-1}{\sigma}} \eta_t - 1} \right)$$

$$h(k_t; \gamma, \phi, \sigma) = \left(\sigma + \frac{1-\phi}{\phi} \frac{1-\gamma(1-\sigma)}{\gamma} k_t^{\frac{1-\sigma}{\sigma}} \right)^{-1}$$

Due to the logarithm, we have two vertical asymptotes depending on whether the numerator or the denominator within the logarithm is equal to zero. The first vertical asymptote is the one associated to the numerator $k_1 = \frac{K_t}{N_t^y}$ and the second vertical asymptote is associated to the denominator $k_2 = \left(\frac{1-\phi}{\phi} \frac{1}{\eta_t} \right)^{\frac{\sigma}{\sigma-1}}$. Rewriting the g function with these vertical asymptotes, I have:

$$g(k_t, k_1, k_2; \sigma) = \ln \left(\frac{\frac{k_t}{k_1} - 1}{\left(\frac{k_t}{k_2} \right)^{\frac{\sigma-1}{\sigma}} - 1} \right)$$

This function has four different shapes according to the value of σ and both vertical asymptotes (k_1 and k_2). Figure 24 plots these shapes. The h function has three different shapes according to the value of σ . Figure 25 plots these shapes.

Proposition 1 *If $k_t \leq k_1$ at the equilibrium, then:*

- (i) *there is a unique equilibrium with full employment where $k_t = k_1$,*
- (ii) *the net wage equals the unemployment benefits, i.e. $(1 - \tau_t)w_t = b_t$.*

Proof. The numerator of the g function is positive if and only if $k_t > k_1 \Leftrightarrow L_t < N_t^y$ (i.e. the number of worker is smaller than the young population size). This condition is always satisfied when there is unemployment. However, if this condition is not satisfied, it would mean that the labor demand exceeds the labor force (i.e. $L_t^d > N_t^y$). Therefore, the economy should face full-employment (i.e. $L_t = N_t^y$) and the capital-per-worker at the equilibrium with full-employment is $k_t = k_1$. In such a case, X_t would tend to $-\infty$. However, the lower bound of X_t is 0. Because if X_t is negative, the unemployment benefits would exceed the net wage. I consider that such a case is not possible.⁴¹ Thus, if $k_t \leq k_1 \Rightarrow k_t = k_1 \Rightarrow u_t = 0 \Rightarrow X_t = 0 \Rightarrow (1 - \tau_t)w_t = b_t$. ■

⁴¹Even though I consider a model with inelastic labor supply, no agent would work for a wage which is lower than unemployment benefits. This assumption can be considered as an incentive constraint.

Figure 24: Different possible shapes of the g function, according to the value of σ, k_1, k_2

The x-axis corresponds to k_t . The function graphs are drawn using numerical computation with the following set of parameters for each case:

- (a) $\sigma = 0.8, k_1 = 1, k_2 = 2$; (b) $\sigma = 0.8, k_1 = 2, k_2 = 1$;
(c) $\sigma = 1.2, k_1 = 1, k_2 = 2$; (d) $\sigma = 1.2, k_1 = 2, k_2 = 1$.

Therefore, the equilibrium with unemployment requires $k_t > k_1$. Hence, any equilibrium in the case represented in figure 24b leads to the equilibrium with full-employment.

I normalize k_t to the vertical asymptote k_1 . Let $\nu = k_2/k_1$ with $\nu > 0$. It implies that $k_2 \geq k_1$ when $\nu \geq 1$. Let $\tilde{k}_t = k_t/k_1$ with $\tilde{k}_t > 0$. As for ν , if \tilde{k}_t is greater than unity, then $k_t > k_1$ and vice-versa. To simplify the notation, let $\rho = \frac{\sigma-1}{\sigma} \in (-\infty, 1)$.⁴² Using this specification, it is possible to rewrite g such that:

$$g(\tilde{k}_t; \nu, \rho) = \ln \left(\frac{\tilde{k}_t - 1}{\tilde{k}_t^\rho - \nu^\rho} \right) + \rho \ln(\nu)$$

⁴²When both input factors are gross complement, the elasticity of substitution is $\sigma \in (0, 1)$ and the corresponding interval for ρ is $(-\infty, 0)$. However, when both are gross substitute, the elasticity of substitution is $\sigma \in (0, +\infty)$ and the corresponding interval for ρ is $(0, 1)$.

Figure 25: Different possible shapes of the h function, according to the value of σ

The x-axis corresponds to k_t . Scales are different according to the graph. The functions graphs are drawn using numerical computation with following set of parameters for each case:

(a) $\sigma = 0.25$, $\phi = 0.3$, $\gamma = 0.5$; (b) $\sigma = 0.8$, $\phi = 0.3$, $\gamma = 0.5$; (c) $\sigma = 1.2$, $\phi = 0.3$, $\gamma = 0.5$.

Let also rewrite the h function such that:

$$h(\tilde{k}_t; \tilde{\gamma}, \rho) = \left(\frac{1}{1-\rho} + \tilde{\gamma} \tilde{k}_t^{-\rho} \right)^{-1}$$

where $\tilde{\gamma} \equiv \frac{1-\phi}{\phi} \frac{1-\gamma(1-\sigma)}{\gamma} k_1^{-\rho} > 0$.

A.1 Under gross-complementarity, i.e. $\rho < 0$

$g(\tilde{k}_t)$ is define and continuous between both vertical asymptotes within the logarithm, so 1 and ν .⁴³ When ν is greater than unity, $g(\tilde{k}_t)$ is defined and continuous on $(1, \nu)$. While the function is defined and continuous on $(\nu, 1)$ when $\nu < 1$. Finally, when $\nu = 1$, \tilde{k}_t can take a unique value which corresponds to 1. This definition domain is due to the properties of the logarithm. Both parts of the product within the logarithm must have the same sign in order to remain defined. The g function has two possible shapes according to the value of ν with respect to unity:

1. if $\nu > 1$:

- (a) $g(\tilde{k}_t)$ is strictly increasing in \tilde{k}_t ,
- (b) $\lim_{\tilde{k}_t \rightarrow 1} g(\tilde{k}_t) = -\infty$ and $\lim_{\tilde{k}_t \rightarrow \nu} g(\tilde{k}_t) = +\infty$.

2. if $\nu < 1$:

⁴³These vertical asymptotes correspond to k_1 and k_2 before the normalization.

- (a) $g(\tilde{k}_t)$ is strictly decreasing in \tilde{k}_t ,
- (b) $\lim_{\tilde{k}_t \rightarrow 1} g(\tilde{k}_t) = +\infty$ and $\lim_{\tilde{k}_t \rightarrow \nu} g(\tilde{k}_t) = -\infty$.

When $\rho < 0$, the h function is defined and continuous on \mathbb{R}_+ and has the following properties:

- 1. $h(\tilde{k}_t)$ is strictly decreasing in \tilde{k}_t ,
- 2. $\lim_{\tilde{k}_t \rightarrow 0} h(\tilde{k}_t) = 1 - \rho$ and $\lim_{\tilde{k}_t \rightarrow +\infty} h(\tilde{k}_t) = 0$.

These properties leads to lemmas 1 and 2. Using these intermediate results with proposition 1, I can prove proposition 1.

Lemma 1 *if $\rho < 0$ and $\nu > 1$, then it exists a unique equilibrium.*

Proof. Let $\rho < 0$ and $\nu > 1$. The g function is defined and continuous in $\tilde{k}_t \in (1, \nu)$, strictly increasing and has two infinite vertical asymptotes of opposite signs. The h function is defined and continuous in $\tilde{k}_t \in \mathbb{R}_+ \supset (1, \nu)$, strictly decreasing and has two finite horizontal asymptotes $1/\sigma$ and 0. Therefore, both functions intersect in only one point. Hence, there is uniqueness of the equilibrium. ■

Lemma 2 *if $\rho < 0$ and $\nu < 1$, then it exists at least one equilibrium.*

Proof. Let $\rho < 0$ and $\nu > 1$. The g function is defined and continuous in $\tilde{k}_t \in (\nu, 1)$, strictly decreasing and has two infinite vertical asymptotes of opposite signs. The h function is defined and continuous in $\tilde{k}_t \in \mathbb{R}_+ \supset (\nu, 1)$, strictly decreasing and has two finite horizontal asymptotes $1 - \rho$ and 0. Therefore, both functions intersect in at least one point. Hence, there is at least one equilibrium. ■

Proposition 2 *if $\rho < 0$, then it exists a unique equilibrium.*

Proof. Lemma 1 claims that there is a unique equilibrium when $\nu > 1$. There is also a unique equilibrium when $\nu = 1$. Lemma 2 asserts that there is at least one equilibrium when $\nu < 1$. Yet, proposition 1 states that any equilibrium when $\nu > 1$ leads to the unique equilibrium with full-employment. Therefore, if $\rho < 0$ there is a unique equilibrium. ■

A.2 Under gross-substituability, i.e $0 < \rho < 1$

Contrary to the previous case, $g(\tilde{k}_t)$ is defined and continuous on \mathbb{R}_+ but outside of both vertical asymptotes within the logarithm, so 1 and ν . When ν is greater than unity, $g(\tilde{k}_t)$ is defined and continuous on $(0, 1) \cap (\nu, +\infty)$. While the function is defined and continuous on $(0, \nu) \cap (1, +\infty)$ when $\nu < 1$. Finally, when $\nu = 1$, the function is defined and continuous

Figure 26: Numerical simulation of g (solid line) and h (dashed line), according to the values of σ and ν

The x-axis corresponds to \tilde{k}_t . The dotted lines correspond to $1 - \rho$, so the infinite limit in \tilde{k}_t of the h function.

on \mathbb{R}_+ but has no longer infinite discontinuity. Regardless of the value of ν , $\lim_{\tilde{k}_t \rightarrow 0} = 0$ and $\lim_{\tilde{k}_t \rightarrow +\infty} = +\infty$. Both vertical asymptotes correspond to $\lim_{\tilde{k}_t \rightarrow 1} g(\tilde{k}_t) = -\infty$ and $\lim_{\tilde{k}_t \rightarrow \nu} g(\tilde{k}_t) = +\infty$. The g function has two possible shapes according to the value of ν with respect to unity.⁴⁴ Moreover, $g(\tilde{k}_t)$ is strictly increasing in \tilde{k}_t when $\nu < 1$. When $\rho > 1$, the h function is defined and continuous on \mathbb{R}_+ and has the following properties:

1. $h(\tilde{k}_t)$ is strictly increasing in \tilde{k}_t ,
2. $\lim_{\tilde{k}_t \rightarrow 0} h(\tilde{k}_t) = 0$ and $\lim_{\tilde{k}_t \rightarrow +\infty} h(\tilde{k}_t) = 1 - \rho$.

I plot both functions with numerical computation for feasible values of σ according to the model conditions as detailed in section 2.4. The parameters γ and ϕ are set according to the calibration in section 3.1, thus $\gamma = 0.5$ and $\phi = 0.3$.⁴⁵ Figure 26 shows both functions in the case where $\nu < 1$. Looking at the behavior of both functions, they do intersect in only one point beyond 1. Therefore, I make the following conjecture:

Conjecture 1 *if $\rho \in (0, 1)$ and $\nu < 1$, then it exists a unique equilibrium.*

This unique equilibrium is the one with unemployment since it lies beyond 1 and therefore beyond k_1 without normalization. I also do the numerical computation in the case where $\nu > 1$, with the same values for γ and ϕ . Figure 27 plots the result. Looking at the behavior of both functions, they do intersect two times before 1. Therefore, I make the following conjecture:

⁴⁴Excluding the case where $\nu = 1$.

⁴⁵The exact values for ϕ are 0.27 for France and 0.325 for the United-States. I use 0.3 for this numerical computation as an approximation of the mean.

Figure 27: Numerical simulation of g (solid line) and h (dashed line), according to the values of σ and ν

The x-axis corresponds to \tilde{k}_t . The dotted lines correspond to $1 - \rho$, so the infinite limit in \tilde{k}_t of the h function.

Conjecture 2 *if $\rho \in (0, 1)$ and $\nu > 1$, then it exists at least one equilibrium lying below unity.*

Using these two conjectures with proposition 1, I can prove that there is a unique equilibrium for all $\rho \in (0, 1)$.⁴⁶

Proposition 3 *if $\rho \in (0, 1)$, then it exists a unique equilibrium.*

Proof. Conjecture 1 claims that there is a unique equilibrium when $\nu < 1$. Conjecture 2 asserts that there is at least one equilibrium when $\nu > 1$ lying below unity. Thus, there is at least one equilibrium such that $k_t < k_1$. Yet, proposition 1 states that any equilibrium with $k_t \leq k_1$ leads to the unique equilibrium with full-employment. Therefore, if $\rho \in (0, 1)$ there is a unique equilibrium. ■

Appendix B. Derivatives

I derive the partial derivative of both functions g and h that determine the equilibrium.

B.1 The g function's derivatives

$$g(L_t, K_t, \eta_t, N_t^y; \phi, \sigma) = \ln \left[\frac{\frac{N_t^y}{L_t} - 1}{\frac{\phi}{1-\phi} \left(\frac{K_t}{L_t} \right)^{\frac{\sigma-1}{\sigma}} \eta_t - 1} \right]$$

⁴⁶Except in the case where $\nu = 1$, i.e. $k_1 = k_2$. In such a case, the infinite discontinuity disappears and so does the equilibrium.

The partial derivative of the g function with respect to η_t is:

$$g_\eta = -\frac{\frac{\phi}{1-\phi}k_t^{\frac{\sigma-1}{\sigma}}}{\frac{\phi}{1-\phi}k_t^{\frac{\sigma-1}{\sigma}}\eta_t - 1} = -(\eta_t - \Theta_t)^{-1} < 0$$

where $\eta_t/\Theta_t - 1$ corresponds to the denominator within the logarithm of the g function. At the equilibrium with unemployment, the denominator must be positive. Therefore $\eta_t - \Theta_t > 0 \implies g_\eta < 0$. The partial derivative of the g function with respect to N_t^y is:

$$g_{N^y} = (N_t^y - L_t)^{-1} > 0$$

At the equilibrium with unemployment, the young population size exceeds the number of workers. Thus, $N_t^y - L_t > 0 \implies g_{N^y} > 0$. The partial derivative of the g function with respect to K_t is:

$$g_K = -\frac{1}{K_t} \frac{\sigma-1}{\sigma} \frac{\frac{\phi}{1-\phi}k_t^{\frac{\sigma-1}{\sigma}}\eta_t}{\frac{\phi}{1-\phi}k_t^{\frac{\sigma-1}{\sigma}}\eta_t - 1}$$

$$g_K = -\frac{1}{K_t} \frac{\sigma-1}{\sigma} (1 - \Theta_t/\eta_t)^{-1} \leq 0, \forall \sigma \geq 1$$

The sign of the derivative depends on the value of the elasticity of substitution between capital and labor with respect to 1. Finally, the partial derivative of the g function with respect to L_t , after some simplifications, is:

$$g_L = -\frac{1}{N_t^y - L_t} - \frac{1}{\sigma L_t} \left(\frac{\phi}{1-\phi}k_t^{\frac{\sigma-1}{\sigma}}\eta_t - \sigma \right)$$

$$g_L = -\frac{1}{N_t^y - L_t} - \frac{1}{\sigma L_t} (\eta_t/\Theta_t - \sigma)$$

At the equilibrium with unemployment, $\eta_t/\Theta_t > 1$. $\eta_t/\Theta_t - \sigma$ is always positive for $\sigma < 1$, thus $g_L < 0 \forall \sigma < 1$. However, the sign cannot be deduced without additional assumptions for $\sigma > 1$. A more restrictive condition is required, i.e. $\eta_t/\Theta_t > \sigma$. In such a case, the partial derivative is unambiguously negative. If this condition is not met, g_L can still be negative provided that the unemployment rate is lower than a threshold $\bar{u}_t = \left(1 - \frac{\eta_t}{\Theta_t \sigma}\right)^{-1}$. Otherwise, g_L is positive.

B.2 The h function's derivatives

$$h(L_t, K_t; \sigma, \phi, \gamma) = \left[\sigma + \frac{1-\phi}{\phi} \frac{1-\gamma(1-\sigma)}{\gamma} \left(\frac{K_t}{L_t} \right)^{\frac{1-\sigma}{\sigma}} \right]^{-1}$$

The partial derivative of the h function with respect to K_t is:

$$h_K = \frac{1}{K_t} \frac{\sigma-1}{\sigma} \frac{\frac{1-\phi}{\phi} \frac{1-\gamma(1-\sigma)}{\gamma} k_t^{\frac{1-\sigma}{\sigma}}}{\left(\sigma + \frac{1-\phi}{\phi} \frac{1-\gamma(1-\sigma)}{\gamma} k_t^{\frac{1-\sigma}{\sigma}} \right)^2} \geq 0, \quad \forall \sigma \geq 1$$

The partial derivative of the h function with respect to L_t is:

$$h_L = -\frac{1}{L_t} \frac{\sigma-1}{\sigma} \frac{\frac{1-\phi}{\phi} \frac{1-\gamma(1-\sigma)}{\gamma} k_t^{\frac{1-\sigma}{\sigma}}}{\left(\sigma + \frac{1-\phi}{\phi} \frac{1-\gamma(1-\sigma)}{\gamma} k_t^{\frac{1-\sigma}{\sigma}} \right)^2} \leq 0, \quad \forall \sigma \geq 1$$

Appendix C. Estimation of σ

The CES production function with biased technical change as defined by [David and van de Klundert \(1965\)](#) is:

$$Y_t = A \left[(E_t^K K_t)^{\frac{\sigma-1}{\sigma}} + (E_t^L L_t)^{\frac{\sigma-1}{\sigma}} \right]^{\frac{\sigma}{\sigma-1}}$$

where E_t^K and E_t^L represent the efficiency levels of both input factors. I assume linear growth rates of efficiency levels, so $E_t^i = E_0^i e^{a_i(t-t_0)}$ where a_i denotes growth in technical progress associated with factor $i \in \{K, L\}$ and represents a linear time trend. To normalize the production function, I follow the specification of [Klump et al. \(2007\)](#),

$$E_0^K = \frac{Y_0}{K_0} \left(\frac{1}{\phi_0} \right)^{\frac{\sigma}{1-\sigma}} \quad \text{and} \quad E_0^L = \frac{Y_0}{L_0} \left(\frac{1}{1-\phi_0} \right)^{\frac{\sigma}{1-\sigma}}$$

Normalization of the CES production function requires that factor shares are not biased by the growth of factor efficiencies at the fixed point. At time $t = t_0$, $e^{a_i(t-t_0)} = 1$. Thus, they are just equal to the initial distribution parameters ϕ_0 and $1 - \phi_0$. Assuming that the firm is on its labor demand curve, as in the model, the labor share at time t is :

$$\theta_t \equiv \frac{w_t L_t}{Y_t} = \left[1 + \left(\frac{E_t^K}{E_t^L} \frac{K_t}{L_t} \right)^{\frac{\sigma-1}{\sigma}} \right]^{-1}$$

Substituting with both efficiency levels, the labor share becomes:

$$\theta_t = \left[1 + \frac{\phi_0}{1 - \phi_0} \left(\frac{K_t}{K_0} \frac{L_0}{L_t} e^{(a_K - a_L)(t - t_0)} \right)^{\frac{\sigma - 1}{\sigma}} \right]^{-1}$$

Let $k_t \equiv K_t/L_t$ the capital-to-labor ratio. Thus, the labor-to-capital income ratio is:

$$\Theta_t \equiv \frac{\theta_t}{1 - \theta_t} = \frac{1 - \phi_0}{\phi_0} \left(\frac{k_t}{k_0} e^{(a_K - a_L)(t - t_0)} \right)^{\frac{1 - \sigma}{\sigma}}$$

Rewriting the above equation and taking logs,

$$\ln \Theta_t = \alpha + \frac{1 - \sigma}{\sigma} \ln \tilde{k}_t + \frac{1 - \sigma}{\sigma} (a_K - a_L) (t - t_0) \quad (19)$$

where \tilde{k}_t is the normalized capital-to-labor ratio and α is constant.

With this form, it is not possible to identify each technical change growth rate (i.e. a_K and a_L). However, it captures the overall bias in technical change (i.e. $a_K - a_L$). I estimate equation (19) using OLS for France and United States over the period 1970-2010.⁴⁷ I use data and variables specifications as described in section 3.1. I consider four specifications. The first one is the RAW estimation, without biased technical change nor hours worked correction. Then, I only control for the average hours worked in the HWC estimation and for the biased technical change in the BTC estimation. Finally, both are used as control in the HWC-BTC estimation. Standard errors are relatively high due to the lack of observations. Equations are estimated by country with 41 observations for each one. When the coefficient associated to the line $\frac{1 - \sigma}{\sigma}$ is not significant it means that the estimated elasticity is not statistically different from 1, i.e. the Cobb-Douglas case. Tables 3 and 4 summarize the results for France and the United States, respectively. For France, worked hours seems to play a role in the estimation of the elasticity when I compare RAW to HWC. Not considering the hours worked correction may bias the elasticity of substitution toward relatively high values (2.593 against 1.887). I compare RAW to BTC and conclude that biased technical change has also to be taken into account. Even though the σ associated coefficient is not significant, the biased technical change's coefficient is significant. Finally, controlling for both in HWC-BTC leads to an elasticity about 1.279. But it is only significant at a 90 % confidence level. This is the result of a break in the regime as explained in [appendix D](#).

⁴⁷This is a single-equation estimation from the two first-order conditions of the profit maximization. As [Klump et al. \(2007\)](#) discussed, single-equation or two-equations estimations can be biased due to endogeneity. They recommend to use supply-side system estimation. However, the aim of this estimation is only to obtain a value to simulate the model. Therefore, the elasticity of substitution I obtain is the one within the model specification.

Table 3: Estimation of the capital-labor elasticity of substitution (σ) for France (1970-2010)

	RAW	HWC	BTC	HWC-BTC
α	1.130*** (0.027)	1.123*** (0.027)	1.081*** (0.035)	1.079*** (0.033)
$\frac{1-\sigma}{\sigma}$	-0.614*** (0.045)	-0.470*** (0.033)	-0.273 (0.165)	-0.218* (0.125)
$\frac{1-\sigma}{\sigma}(a_K - a_L)$			-0.007** (0.003)	-0.007** (0.003)
Biased technical change	No	No	Yes	Yes
Hours worked correction	No	Yes	No	Yes
σ	2.593	1.887	1.375	1.279

Note : *p<0.1; **p<0.05; ***p<0.01. Robust standard errors in parentheses.

The biased technical change coefficient is also significant as in BTC. It indicates that biased technical change has to be jointly considered with the hours worked for France.

For the United States, hours worked correction does matter by comparing RAW to HWC. Once I control for it, the elasticity of substitution is about 1.234. However, the technical change does not seem to be biased since both associated coefficients in BTC and HWC-BTC are not significant. The coefficient associated to the elasticity are below unity but not statistically significant. Thus, controlling for biased technical change is not necessary for the United States. I only have to control for average worked hours. Therefore, I consider a capital-labor elasticity of substitution about 1.279 for France and 1.234 for the United States. These σ values are used to compute the deduced parameter values (i.e. ω and β) in section 3.1.

Appendix D. Two σ regimes in France

Considering the estimation methodology in [appendix C](#), I obtain a capital-labor elasticity of substitution around 1.279 for France over the period 1970-2010. However, the estimated coefficient is only significant at a 90% confidence level. Such a result may be due to a break in the regime of σ . The relationship between the labor-to-capital income ratio Θ_t and the capital-per-worker k_t depends on the value of σ with respect to unity. From the comparatives

Table 4: Estimation of the capital-labor elasticity of substitution (σ) for the United States (1970-2010)

	RAW	HWC	BTC	HWC-BTC
α	0.636*** (0.020)	0.648*** (0.022)	0.643*** (0.022)	0.649*** (0.021)
$\frac{1-\sigma}{\sigma}$	-0.177** (0.073)	-0.189*** (0.067)	0.155 (0.473)	-0.647* (0.348)
$\frac{1-\sigma}{\sigma}(a_K - a_L)$			-0.004 (0.006)	0.006 (0.005)
Biased technical change	No	No	Yes	Yes
Hours worked correction	No	Yes	No	Yes
σ	1.215	1.234	0.866	2.835

Note : *p<0.1; **p<0.05; ***p<0.01. Robust standard errors in parentheses.

statics derived in section 2, it can be shown that :

$$\frac{\partial \Theta_t}{\partial k_t} \begin{matrix} \geq \\ \leq \end{matrix} 0 \quad \text{when} \quad \sigma \begin{matrix} \leq \\ > \end{matrix} 1$$

When both input factors are gross complement (i.e. $\sigma < 1$), the labor-to-capital income ratio and the capital-per-worker vary in the same direction. While they vary in opposite ways under gross substitutability. The elasticity of substitution σ is estimated using the following equation :

$$\ln \Theta_t = \alpha + \frac{1-\sigma}{\sigma} \ln \tilde{k}_t + \frac{1-\sigma}{\sigma} (a_K - a_L) (t - t_0)$$

Inspecting the time series of $\ln \Theta_t$ and $\ln \tilde{k}_t$, I suspect that there is a change of regime in the link between them. Figure 28 plots these time series. The figure suggests that the correlation between both variables is different before and after the beginning of the 80's. Suppose that the change of regime in the relationship has occurred in 1982. The correlation between both variables is about 0.305 before 1982 and -0.787 after.⁴⁸ Such a difference in the correlation suggests that there are two regimes. However, the biased technical change has not been considered so far. Therefore, I have to detrend both variables in order to check whether the regime change is not driven by it. Using the Frisch-Waugh-Lovell theorem, I regress each variable on a linear time trend and extract the residuals as detrended variables. Both

⁴⁸The year 1982 is included in the first sub-sample. Including it in the sub-sample after the break leads to the correlations of 0.499 and -0.786 for before and after respectively.

Figure 28: $\ln \tilde{k}_t$ (solid) and $\ln \Theta_t$ (dashed) for France over the period 1970-2010

regressions correspond to the following:

$$\begin{aligned}\ln \Theta_t &= \varphi_0^\Theta + \varphi_1^\Theta \times t + \varepsilon_t^\Theta \\ \ln \tilde{k}_t &= \varphi_0^{\tilde{k}} + \varphi_1^{\tilde{k}} \times t + \varepsilon_t^{\tilde{k}}\end{aligned}$$

Figure 29 displays both detrended variables $\varepsilon_t^{\tilde{k}}$ and ε_t^Θ . The vertical dashed lines correspond to potential break years in the regime. Looking at the variables behavior before and after the three thresholds, it suggests that there are still two regimes. Therefore, this result remains even when controlling for linear biased technical change.

For instance, figure 30 plots the regression lines before and after an elasticity regime change in 1985. The slope is positive between 1970 and 1985, so the elasticity would be smaller than 1 during this period and greater thereafter. All years between 1980 and 1990 are candidate to be the break year.

To find which year corresponds to the most efficient break year, I run multiple regressions by changing the break year \bar{t} for each regression. The estimated equation is:

$$\varepsilon_t^\Theta = \nu_1 \mathbb{1}_{\{t \leq \bar{t}\}} + \nu_2 \mathbb{1}_{\{t > \bar{t}\}} + \rho_1 \mathbb{1}_{\{t \leq \bar{t}\}} \varepsilon_t^{\tilde{k}} + \rho_2 \mathbb{1}_{\{t > \bar{t}\}} \varepsilon_t^{\tilde{k}} + \zeta_t$$

where $\mathbb{1}$ is a dummy variable which is equal to 1 when the condition under brackets is satisfied, 0 otherwise. Table 5 displays the four coefficients (i.e. ν_1 , ν_2 , ρ_1 , ρ_2) and the R^2 of each regression. The regression with a change in the regime in 1985 (i.e. $\bar{t} = 1985$) has

Figure 29: $\tilde{\varepsilon}_t^k$ (solid) and ε_t^Θ (dashed) for France over the period 1970-2010

the greatest R^2 and all its coefficients are significant. Thus, I assume that the break in the regime has occurred in 1985. I have to estimate a value of σ for 1970-1985 and another one for 1986-2010. I estimate the equation (19) for each sub-sample with and without biased technical change. Table 6 summarizes the results. Biased technical change coefficients are not significant in both sub-sample regressions, neither are the coefficients associated to the elasticity. Therefore, I take into account the estimate where the technical change is not biased. Between 1970 and 1985, I set the capital-labor elasticity of substitution to unity, since the coefficient is not statistically different from 0.⁴⁹ However, it is significant between 1986 and 2010 and the elasticity is about 1.321.

⁴⁹This is mainly due to the lack of observations. The sub-sample has only 16 observations and therefore 14 degrees of freedom.

Figure 30: Relationship between $\varepsilon_t^{\bar{k}}$ (x-axis) and ε_t^{Θ} (y-axis) for France over the period 1970-2010

The gray area corresponds to the confidence interval of the associated regression. The level of the confidence interval is set to 0.95.
